We wish to thank Thomas Thom, Jonathan Pool, Michael Wolz, and Sean Coady for their valuable comments and contributions. We would like to acknowledge Karen Modesitt for her administrative assistance.

### Summary

Each year, the American Heart Association (AHA), in conjunction with the Centers for Disease Control and Prevention, the National Institutes of Health, and other government agencies, brings together the most up-to-date statistics on heart disease, stroke, other vascular diseases, and their risk factors and presents them in its Heart Disease and Stroke Statistical Update. The Statistical Update is a valuable resource for researchers, clinicians, healthcare policy makers, media professionals, the lay public, and many others who seek the best national data available on disease morbidity and mortality and the risks, quality of care, medical procedures and operations, and costs associated with the management of these diseases in a single document. Indeed, since 1999, the Statistical Update has been cited more than 8700 times in the literature (including citations of all annual versions). In 2009 alone, the various Statistical Updates were cited  $\approx$ 1600 times (data from ISI Web of Science). In recent years, the Statistical Update has undergone some major changes with the addition of new chapters and major updates across multiple areas. For this year's edition, the Statistics Committee, which produces the document for the AHA, updated all of the current chapters with the most recent nationally representative data and inclusion of relevant articles from the literature over the past year and added a new chapter detailing how family history and genetics play a role in cardiovascular disease (CVD) risk. Also, the 2011 Statistical Update is a major source for monitoring both cardiovascular health and disease in the population, with a focus on progress toward achievement of the AHA's 2020 Impact Goals. Below are a few highlights from this year's Update.

#### ***Death Rates From CVD Have Declined, Yet the Burden of Disease Remains High***

- The 2007 overall death rate from CVD (*International Classification of Diseases 10*, I00–I99) was 251.2 per 100 000. The rates were 294.0 per 100 000 for white males, 405.9 per 100 000 for black males, 205.7 per 100 000 for white females, and 286.1 per 100 000 for black females. From 1997 to 2007, the death rate from CVD declined 27.8%. Mortality data for 2007 show that CVD (I00–I99; Q20–Q28) accounted for 33.6% (813 804) of all 2 243 712 deaths in 2007, or 1 of every 2.9 deaths in the United States.
- On the basis of 2007 mortality rate data, more than 2200 Americans die of CVD each day, an average of 1 death every 39 seconds. More than 150 000 Americans killed by

CVD (I00–I99) in 2007 were  $<$ 65 years of age. In 2007, nearly 33% of deaths due to CVD occurred before the age of 75 years, which is well before the average life expectancy of 77.9 years.

- Coronary heart disease caused  $\approx$ 1 of every 6 deaths in the United States in 2007. Coronary heart disease mortality in 2007 was 406 351. Each year, an estimated 785 000 Americans will have a new coronary attack, and  $\approx$ 470 000 will have a recurrent attack. It is estimated that an additional 195 000 silent first myocardial infarctions occur each year. Approximately every 25 seconds, an American will have a coronary event, and approximately every minute, someone will die of one.
- Each year,  $\approx$ 795 000 people experience a new or recurrent stroke. Approximately 610 000 of these are first attacks, and 185 000 are recurrent attacks. Mortality data from 2007 indicate that stroke accounted for  $\approx$ 1 of every 18 deaths in the United States. On average, every 40 seconds, someone in the United States has a stroke. From 1997 to 2007, the stroke death rate fell 44.8%, and the actual number of stroke deaths declined 14.7%.
- In 2007, 1 in 9 death certificates (277 193 deaths) in the United States mentioned heart failure.

#### ***Prevalence and Control of Traditional Risk Factors Remains an Issue for Many Americans***

- Data from the National Health and Nutrition Examination Survey (NHANES) 2005–2008 indicate that 33.5% of US adults  $\geq$ 20 years of age have hypertension (Table 7-1). This amounts to an estimated 76 400 000 US adults with hypertension. The prevalence of hypertension is nearly equal between men and women. African American adults have among the highest rates of hypertension in the world, at 44%. Among hypertensive adults,  $\approx$ 80% are aware of their condition, 71% are using antihypertensive medication, and only 48% of those aware that they have hypertension have their condition controlled.
- Despite 4 decades of progress, in 2008, among Americans  $\geq$ 18 years of age, 23.1% of men and 18.3% of women continued to be cigarette smokers. In 2009, 19.5% of students in grades 9 through 12 reported current tobacco use. The percentage of the nonsmoking population with detectable serum cotinine (indicating exposure to second-hand smoke) was 46.4% in 1999 to 2004, with declines occurring, and was highest for those 4 to 11 years of age (60.5%) and those 12 to 19 years of age (55.4%).
- An estimated 33 600 000 adults  $\geq$ 20 years of age have total serum cholesterol levels  $\geq$ 240 mg/dL, with a prevalence of 15.0% (Table 13-1).
- In 2008, an estimated 18 300 000 Americans had diagnosed diabetes mellitus, representing 8.0% of the adult population. An additional 7 100 000 had undiagnosed diabetes mellitus, and 36.8% had prediabetes, with abnormal fasting glucose levels. African Americans, Mexican Americans, Hispanic/Latino individuals, and other ethnic minorities bear a strikingly disproportionate burden of diabetes mellitus in the United States (Table 16-1).

#### ***The 2011 Update Expands Data Coverage of the Obesity Epidemic and Its Antecedents and Consequences***

- The estimated prevalence of overweight and obesity in US adults ( $\geq$ 20 years of age) is 149 300 000, which represents 67.3% of this group in 2008. Fully 33.7% of US adults are

obese (body mass index  $\geq 30$  kg/m<sup>2</sup>). Men and women of all race/ethnic groups in the population are affected by the epidemic of overweight and obesity (Table 15-1).

- Among children 2 to 19 years of age, 31.9% are overweight and obese (which represents 23 500 000 children), and 16.3% are obese (12 000 000 children). Mexican American boys and girls and African American girls are disproportionately affected. Over the past 3 decades, the prevalence of obesity in children 6 to 11 years of age has increased from  $\approx 4\%$  to more than 20%.
- Obesity (body mass index  $\geq 30$  kg/m<sup>2</sup>) is associated with marked excess mortality in the US population. Even more notable is the excess morbidity associated with overweight and obesity in terms of risk factor development and incidence of diabetes mellitus, CVD end points (including coronary heart disease, stroke, and heart failure), and numerous other health conditions, including asthma, cancer, degenerative joint disease, and many others.
- The prevalence of diabetes mellitus is increasing dramatically over time, in parallel with the increases in prevalence of overweight and obesity.
- On the basis of NHANES 2003–2006 data, the age-adjusted prevalence of metabolic syndrome, a cluster of major cardiovascular risk factors related to overweight/obesity and insulin resistance, is 34% (35.1% among men and 32.6% among women).
- The proportion of youth ( $\leq 18$  years of age) who report engaging in no regular physical activity is high, and the proportion increases with age. In 2007, among adolescents in grades 9 through 12, 29.9% of girls and 17.0% of boys reported that they had not engaged in 60 minutes of moderate-to-vigorous physical activity, defined as any activity that increased heart rate or breathing rate, even once in the previous 7 days, despite recommendations that children engage in such activity  $\geq 5$  days per week.
- Thirty-six percent of adults reported engaging in no vigorous activity (activity that causes heavy sweating and a large increase in breathing or heart rate).
- Data from NHANES indicate that between 1971 and 2004, average total energy consumption among US adults increased by 22% in women (from 1542 to 1886 kcal/d) and by 10% in men (from 2450 to 2693 kcal/d; see Chart 19-1).
- The increases in calories consumed during this time period are attributable primarily to greater average carbohydrate intake, in particular, of starches, refined grains, and sugars. Other specific changes related to increased caloric intake in the United States include larger portion sizes, greater food quantity and calories per meal, and increased consumption of sugar-sweetened beverages, snacks, commercially prepared (especially fast food) meals, and higher energy-density foods.

### ***The 2011 Update Provides Critical Data Regarding Cardiovascular Quality of Care, Procedure Utilization, and Costs***

In light of the current national focus on healthcare utilization, costs, and quality, it is critical to monitor and understand the magnitude of healthcare delivery and costs, as well as the quality of healthcare delivery, related to CVDs. The Update provides these critical data in several sections.

#### ***Quality-of-Care Metrics for CVDs***

Chapter 20 reviews many metrics related to the quality of care delivered to patients with CVDs, as well as healthcare disparities. In particular, quality data are available from the

AHA's "Get With The Guidelines" programs for coronary artery disease and heart failure and the American Stroke Association/ AHA's "Get With the Guidelines" program for acute stroke. Similar data from the Veterans Healthcare Administration, national Medicare and Medicaid data and National Cardiovascular Data Registry Acute Coronary Treatment and Intervention Outcomes Network - "Get With The Guidelines" Registry data are also reviewed. These data show impressive adherence with guideline recommendations for many, but not all, metrics of quality of care for these hospitalized patients. Data are also reviewed on screening for cardiovascular risk factor levels and control.

#### ***Cardiovascular Procedure Utilization and Costs***

Chapter 21 provides data on trends and current usage of cardiovascular surgical and invasive procedures. For example, the total number of inpatient cardiovascular operations and procedures increased 27%, from 5 382 000 in 1997 to 6 846 000 in 2007 (National Heart, Lung, and Blood Institute computation based on National Center for Health Statistics annual data).

Chapter 22 reviews current estimates of direct and indirect healthcare costs related to CVDs, stroke, and related conditions using Medical Expenditure Panel Survey data. The total direct and indirect cost of CVD and stroke in the United States for 2007 is estimated to be \$286 billion. This figure includes health expenditures (direct costs, which include the cost of physicians and other professionals, hospital services, prescribed medications, home health care, and other medical durables) and lost productivity resulting from mortality (indirect costs). By comparison, in 2008, the estimated cost of all cancer and benign neoplasms was \$228 billion (\$93 billion in direct costs, \$19 billion in morbidity indirect costs, and \$116 billion in mortality indirect costs). CVD costs more than any other diagnostic group.

The AHA, through its Statistics Committee, continuously monitors and evaluates sources of data on heart disease and stroke in the United States to provide the most current data available in the Statistics Update. The 2007 mortality data have been released. More information can be found at the National Center for Health Statistics Web site, [http://www.cdc.gov/nchs/data/nvsr/nvsr58/nvsr58\\_01.pdf](http://www.cdc.gov/nchs/data/nvsr/nvsr58/nvsr58_01.pdf).

Finally, it must be noted that this annual Statistical Update is the product of an entire year's worth of effort by dedicated professionals, volunteer physicians and scientists, and outstanding AHA staff members, without whom publication of this valuable resource would be impossible. Their contributions are gratefully acknowledged.

*Véronique L. Roger, MD, MPH, FAHA*

*Melanie B. Turner, MPH*

*On behalf of the American Heart Association Heart Disease and Stroke Statistics Writing Group*

Note: Population data used in the compilation of NHANES prevalence estimates is for the latest year of the NHANES survey being used. Extrapolations for NHANES prevalence estimates are based on the census resident population for 2008 because this is the most recent year of NHANES data used in the Statistical Update.

KEY WORDS: AHA Statistical Update ■ cardiovascular diseases ■ epidemiology ■ risk factors ■ statistics ■ stroke

This table represents the relationships of writing group members that may be perceived as actual or reasonably perceived conflicts of interest as reported on the Disclosure Questionnaire, which all members of the writing group are required to complete and submit. A relationship is considered to be "significant" if (a) the person receives \$10 000 or more during any 12-month period, or 5% or more of the person's gross income; or (b) the person owns 5% or more of the voting stock or share of the entity, or owns \$10 000 or more of the fair market value of the entity. A relationship is considered to be "modest" if it is less than "significant" under the preceding definition.

\*Modest.

†Significant.

## 1. About These Statistics

The American Heart Association (AHA) works with the Centers for Disease Control and Prevention's (CDC's) National Center for Health Statistics (NCHS); the National Heart, Lung, and Blood Institute (NHLBI); the National Institute of Neurological Disorders and Stroke (NINDS); and other government agencies to derive the annual statistics in this Update. This chapter describes the most important sources and the types of data we use from them. For more details, see Chapter 24 of this document, the Glossary.

The surveys used are:

- Behavioral Risk Factor Surveillance System (BRFSS)—ongoing telephone health survey system
- Greater Cincinnati/Northern Kentucky Stroke Study (GCNKSS)—stroke incidence rates and outcomes within a biracial population
- Medical Expenditure Panel Survey (MEPS)—data on specific health services that Americans use, how frequently they use them, the cost of these services, and how the costs are paid

### Abbreviations Used in Chapter 1

AHA	American Heart Association
AHRQ	Agency for Healthcare Research and Quality
AP	angina pectoris
ARIC	Atherosclerosis Risk in Communities Study
BP	blood pressure
BRFSS	Behavioral Risk Factor Surveillance System
CDC	Centers for Disease Control and Prevention
CHS	Cardiovascular Health Study
CVD	cardiovascular disease
ED	emergency department
FHS	Framingham Heart Study
GCNKSS	Greater Cincinnati/Northern Kentucky Stroke Study
HF	heart failure
ICD	International Classification of Diseases
<i>ICD-9-CM</i>	<i>International Classification of Diseases, Clinical Modification, 9th Revision</i>
MEPS	Medical Expenditure Panel Survey
MI	myocardial infarction
NAMCS	National Ambulatory Medical Care Survey
NCHS	National Center for Health Statistics
NHAMCS	National Hospital Ambulatory Medical Care Survey
NHANES	National Health and Nutrition Examination Survey
NHDS	National Hospital Discharge Survey
NHIS	National Health Interview Survey
NHLBI	National Heart, Lung, and Blood Institute
NINDS	National Institute of Neurological Disorders and Stroke
NIS	National Inpatient Sample
NNHS	National Nursing Home Survey
OPD	outpatient department
WHO	World Health Organization
YRBSS	Youth Risk Behavior Surveillance System

See Glossary (Chapter 24) for explanation of terms.

- National Health and Nutrition Examination Survey (NHANES)—disease and risk factor prevalence and nutrition statistics
- National Health Interview Survey (NHIS)—disease and risk factor prevalence
- National Hospital Discharge Survey (NHDS)—hospital inpatient discharges and procedures (discharged alive, dead, or status unknown)
- National Ambulatory Medical Care Survey (NAMCS)—physician office visits
- National Hospital Ambulatory Medical Care Survey (NHAMCS)—hospital outpatient and emergency department visits
- National Inpatient Sample (NIS) of the Agency for Healthcare Research and Quality (AHRQ)—hospital inpatient discharges, procedures, and charges
- National Nursing Home Survey (NNHS)—nursing home residents
- National Vital Statistics System—national and state mortality data
- World Health Organization (WHO)—mortality rates by country
- Youth Risk Behavior Surveillance System (YRBSS) (CDC)—health-risk behaviors in youth and young adults

### Disease Prevalence

Prevalence is an estimate of how many people have a disease at a given point or period in time. The NCHS conducts health examination and health interview surveys that provide estimates of the prevalence of diseases and risk factors. In this Update, the health interview part of the NHANES is used for the prevalence of cardiovascular diseases (CVDs). NHANES is used more than the NHIS because in NHANES, angina pectoris (AP) is based on the Rose Questionnaire; estimates are made regularly for heart failure (HF); hypertension is based on blood pressure (BP) measurements and interviews; and an estimate can be made for total CVD, including myocardial infarction (MI), AP, HF, stroke, and hypertension.

A major emphasis of this Update is to present the latest estimates of the number of people in the United States who have specific conditions to provide a realistic estimate of burden. Most estimates based on NHANES prevalence rates are based on data collected from 2005 to 2008 (in most cases, these are the latest published figure). These are applied to census population estimates for 2008. Differences in population estimates based on extrapolations of rates beyond the data collection period by use of more recent census population estimates cannot be used to evaluate possible trends in prevalence. Trends can only be evaluated by comparing prevalence rates estimated from surveys conducted in different years.

### Risk Factor Prevalence

The NHANES 2005–2008 data are used in this Update to present estimates of the percentage of people with high lipid values, diabetes mellitus, overweight, and obesity. The NHIS is used for the prevalence of cigarette smoking and physical inactivity. Data for students in grades 9 through 12 are obtained from the YRBSS.

### Incidence and Recurrent Attacks

An incidence rate refers to the number of new cases of a disease that develop in a population per unit of time. The unit of time for incidence is not necessarily 1 year, although we often discuss incidence in terms of 1 year. For some statistics, new and recurrent attacks or cases are combined. Our national incidence estimates for the various types of CVD are extrapolations to the US population from the Framingham Heart Study (FHS), the Atherosclerosis Risk in Communities (ARIC) study, and the Cardiovascular Health Study (CHS), all conducted by the NHLBI, as well as the GCKSS, which is funded by the NINDS. The rates change only when new data are available; they are not computed annually. Do not compare the incidence or the rates with those in past editions of the Heart Disease and Stroke Statistics Update (also known as the Heart and Stroke Statistical Update for editions before 2005). Doing so can lead to serious misinterpretation of time trends.

### Mortality

Mortality data are presented according to the underlying cause of death. "Any-mention" mortality means that the condition was nominally selected as the underlying cause or was otherwise mentioned on the death certificate. For many deaths classified as attributable to CVD, selection of the single most likely underlying cause can be difficult when several major comorbidities are present, as is often the case in the elderly population. It is useful, therefore, to know the extent of mortality due to a given cause regardless of whether it is the underlying cause or a contributing cause (ie, its "any-mention" status). The number of deaths in 2007 with any mention of specific causes of death was tabulated by the NHLBI from the NCHS public-use electronic files on mortality.

The first set of statistics for each disease in this Update includes the number of deaths for which the disease is the underlying cause. Two exceptions are Chapter 7 (High Blood Pressure) and Chapter 9 (Heart Failure). High BP, or hypertension, increases the mortality risks of CVD and other diseases, and HF should be selected as an underlying cause only when the true underlying cause is not known. In this Update, hypertension and HF death rates are presented in 2 ways: (1) as nominally classified as the underlying cause and (2) as any-mention mortality.

National and state mortality data presented according to the underlying cause of death were computed from the mortality tables of the NCHS World Wide Web site, the Health Data Interactive data system of the NCHS, or the CDC compressed mortality file. Any-mention numbers of deaths were tabulated from the electronic mortality files of the NCHS World Wide Web site and from Health Data Interactive.

### Population Estimates

In this publication, we have used national population estimates from the US Census Bureau for 2008 in the computation of morbidity data. NCHS population estimates for 2007 were used in the computation of death rate data. The Census Bureau World Wide Web site<sup>1</sup> contains these data, as well as information on the file layout.

### Hospital Discharges and Ambulatory Care Visits

Estimates of the numbers of hospital discharges and numbers of procedures performed are for inpatients discharged from short-stay hospitals. Discharges include those discharged alive, dead, or with unknown status. Unless otherwise specified, discharges are listed according to the first-listed (primary) diagnosis, and procedures are listed according to all listed procedures (primary plus secondary). These estimates are from the NHDS of the NCHS unless otherwise noted. Ambulatory care visit data include patient visits to physician offices and hospital outpatient departments (OPDs) and emergency departments (EDs). Ambulatory care visit data reflect the first-listed (primary) diagnosis. These estimates are from NAMCS and NHAMCS of the NCHS.

### International Classification of Diseases

Morbidity (illness) and mortality (death) data in the United States have a standard classification system: the International Classification of Diseases (ICD). Approximately every 10 to 20 years, the ICD codes are revised to reflect changes over time in medical technology, diagnosis, or terminology. Where necessary for comparability of mortality trends across the 9th and 10th ICD revisions, comparability ratios computed by the NCHS are applied as noted.<sup>2</sup> Effective with mortality data for 1999, we are using the 10th revision (ICD-10). It will be a few more years before the 10th revision is used for hospital discharge data and ambulatory care visit data, which are based on the *International Classification of Diseases, Clinical Modification, 9th Revision (ICD-9-CM)*.<sup>3</sup>

### Age Adjustment

Prevalence and mortality estimates for the United States or individual states comparing demographic groups or estimates over time either are age specific or are age adjusted to the 2000 standard population by the direct method.<sup>4</sup> International mortality data are age adjusted to the European standard.<sup>5</sup> Unless otherwise stated, all death rates in this publication are age adjusted and are deaths per 100 000 population.

### Data Years for National Estimates

In this Update, we estimate the annual number of new (incidence) and recurrent cases of a disease in the United States by extrapolating to the US population in 2008 from rates reported in a community- or hospital-based study or multiple studies. Age-adjusted *incidence* rates by sex and race are also given in this report as observed in the study or studies. For US *mortality*, most numbers and rates are for 2007. For disease and risk factor *prevalence*, most rates in this report are calculated from the 2005–2008 NHANES. Rates by age and sex are also applied to the US population in 2008 to estimate the numbers of people with the disease or risk factor in that year. Because NHANES is conducted only in the noninstitutionalized population, we extrapolated the rates to the total US population in 2008, recognizing that this probably underestimates the total prevalence, given the relatively high prevalence in the institutionalized population. The numbers and rates of *hospital inpatient discharges* for the United States are for 2007. Numbers of visits to *physician*

offices, hospital EDs, and hospital OPDs are for 2007. Except as noted, economic cost estimates are for 2007.

### Cardiovascular Disease

For data on hospitalizations, physician office visits, and mortality, CVD is defined according to ICD codes given in Chapter 24 of the present document. This definition includes all diseases of the circulatory system, as well as congenital CVD. Unless so specified, an estimate for total CVD does not include congenital CVD. Prevalence of CVD includes people with hypertension, heart disease, stroke, peripheral artery disease, and diseases of the veins.

### Race

Data published by governmental agencies for some racial groups are considered unreliable because of the small sample size in the studies. Because we try to provide data for as many racial groups as possible, we show these data for informational and comparative purposes.

### Contacts

If you have questions about statistics or any points made in this Update, please contact the AHA National Center, Office

of Science & Medicine at [statistics@heart.org](mailto:statistics@heart.org) or 214-706-1423. Direct all media inquiries to News Media Relations at [inquiries@heart.org](mailto:inquiries@heart.org) or 214-706-1173.

We do our utmost to ensure that this Update is error free. If we discover errors after publication, we will provide corrections at our World Wide Web site, <http://www.americanheart.org/statistics>, and in the journal *Circulation*.

## 2. American Heart Association's 2020 Impact Goals

See Tables 2-1 through 2-3 and Charts 2-1 through 2-7.

After achieving its major Impact Goals for 2010, the AHA recently created a new set of Impact Goals for the current decade.<sup>1</sup> Specifically, the AHA committed to the following organizational goals:

*By 2020, to improve the cardiovascular health of all Americans by 20%, while reducing deaths from cardiovascular disease and stroke by 20%.<sup>1</sup>*

These goals include a novel concept, "cardiovascular health," which encompasses 7 health behaviors and health factors (Table 2-1). "Ideal cardiovascular health" is defined by the absence of clinically manifest cardiovascular disease (CVD) and the simultaneous presence of optimal levels of all 7 health behaviors (lean body mass, avoidance of smoking, participation in physical activity, and healthy dietary intake consistent with a Dietary Approaches to Stop Hypertension [DASH]-like eating pattern) and health factors (untreated total cholesterol <200 mg/dL, untreated blood pressure <120/<80 mm Hg, and fasting blood glucose <100 mg/dL). Because the ideal cardiovascular health profile is known to be rare in the population, the entire spectrum of cardiovascular health can also be represented as being "ideal," "intermediate," or "poor" for each of the health behaviors and health factors, as shown in Table 2-1.<sup>1</sup>

Beginning in 2011, and recognizing the substantial time lag in the nationally representative data sets, the annual Statistical Update will begin to evaluate and publish metrics and information that gives AHA directional insights into progress and/or areas critical for greater concentration, to meet their 2020 goals. In this chapter, baseline data are presented that were derived from the existing national data available on January 20, 2010, the official announcement date of the 2020 Impact Goals.

### Cardiovascular Health

- Table 2-1 provides the specific definitions for ideal, intermediate, and poor cardiovascular health for each of the 7 health behaviors and health factors.

#### Abbreviations Used in Chapter 2

AHA	American Heart Association
BMI	body mass index
BP	blood pressure
CVD	cardiovascular disease
DASH	Dietary Approaches to Stop Hypertension
DBP	diastolic blood pressure
mg/dL	milligrams per deciliter
MI	myocardial infarction
mm Hg	millimeter of mercury
NHANES	National Health and Nutrition Examination Survey
SBP	systolic blood pressure

- The prevalences of ideal, intermediate, and poor levels of each of the 7 cardiovascular health metrics are shown in Chart 2-1 (for children) and Chart 2-2 (for adults).
  - Among children (Chart 2-1), the prevalence (unadjusted) of ideal levels of cardiovascular health behaviors and factors currently varies from 0% for the healthy diet score (ie, essentially no children meet 4 or 5 of the 5 dietary components) to more than 80% for the smoking and fasting glucose metrics. More than 90% of US children meet 0 or only 1 of the 5 healthy dietary components.
  - Among US adults (Chart 2-2), the age-standardized prevalence of ideal levels of cardiovascular health behaviors and factors currently varies from 0.2% for the healthy diet score up to 72% for the smoking metric (ie, 72% of US adults have never smoked or are current nonsmokers who have quit for more than 12 months).
  - In general, the prevalence of ideal levels of health behaviors and health factors is higher in US children than in US adults.
- Age-standardized and age-specific prevalence estimates for Ideal Cardiovascular Health and for ideal levels of each of its components are shown in Table 2-2.
- Chart 2-3 displays the prevalence estimates for the population of US children meeting different numbers of criteria for Ideal Cardiovascular Health (out of 7 possible).
  - Half of US children ages 12 to 19 years meet 4 or fewer criteria for Ideal Cardiovascular Health.
  - The distributions are similar in boys and girls.
- Charts 2-4 and 2-5 display the age-standardized prevalence estimates for the population of US adults meeting different numbers of criteria for Ideal Cardiovascular Health (out of 7 possible), overall, and stratified by age groups, sex, and race.
  - Approximately 3% of US adults have 0 of the 7 criteria at ideal levels, with ≈26% having 3 at ideal levels (Chart 2-4).
  - Compared with younger adults, older adults tend to have fewer of the 7 metrics at ideal levels; more than half of those over age 60 years have only 2 or fewer at ideal levels (Chart 2-4).
  - Women tend to have more metrics at ideal levels than do men (Chart 2-4).
  - Approximately 61% of white adults and 71% of black and Mexican American adults have 3 or fewer metrics (out of 7) at ideal levels (Chart 2-5).
- Chart 2-6 displays the age-standardized percentages of US adults and percentages of children who have 5 or more of the metrics (out of 7 possible) at ideal levels.
  - Almost 50% of US children aged 12 to 19 years have 5 or more metrics at ideal levels, including somewhat more boys than girls.
  - However, only 17% of US adults have 5 or more metrics with ideal levels, including 11% of men and 24% of women.

- Whites have approximately twice the percentage of adults with 5 or more metrics with ideal levels, compared with Mexican Americans.

### Cardiovascular Disease

- In 2006 (baseline data for the 2020 Impact Goals on CVD and stroke mortality), age-standardized death rate from all CVDs was 262.5 per 100 000 (Chart 2-7).
  - Death rates from stroke, heart diseases and other cardiovascular causes were 43.6, 200.2, and 53.9 per 100 000, respectively.<sup>2</sup>
- Data from NHANES 1999–2006 reveal that, overall, 8.1% of Americans self-reported having some type of CVD (Table 2-3).
- Among those with CVD, risk factor prevalence, awareness, treatment, and control were variable (Table 2-3).
  - Nearly 37% were current smokers or had quit for less than 12 months.
  - Awareness and treatment of hypertension were ≈80%, but only two-thirds of those who were treated were controlled to goal levels.
  - Awareness and treatment of hypercholesterolemia were 60% and 68%, respectively, and 80% of treated individuals were at goal cholesterol levels.
  - More than three fourths were overweight or obese, and 45% were obese.
  - 18% had diabetes mellitus.
  - 45% participated in no physical activity.
  - 100% of those with CVD met 3 or fewer of the 5 components of the healthy diet score.

### Implications

- Taken together, these baseline data indicate the substantial progress that will need to occur for the AHA to achieve its 2020 Impact Goals over the next decade.
  - To achieve improvements in cardiovascular health, all segments of the population will need to focus on improved cardiovascular health behaviors, in particular, with regard to diet and weight, as well as on an increase in physical activity and further reduction of the prevalence of smoking.
  - More children, adolescents, and young adults will need to learn how to preserve their ideal levels of cardiovascular health factors and health behaviors into older ages.
  - With regard to reducing the burden of CVD and stroke morbidity and mortality, renewed emphasis will be needed on treatment of acute events as well as secondary and primary prevention through treatment and control of risk factors.
- Future issues of the Statistical Update will track progress toward these goals.

**Table 2-1. Definitions of Poor, Intermediate, and Ideal Cardiovascular Health for Each Metric in the AHA 2020 Goals**

	Level of Cardiovascular Health for Each Metric		
	Poor	Intermediate	Ideal
<b>Current smoking</b>			
Adults aged >20 y	Yes	Former ≤12 mo	Never or quit >12 mo
Children aged 12–19 y	Tried prior 30 d	...	Never tried; never smoked whole cigarette
<b>BMI</b>			
Adults aged >20 y	≥30 kg/m <sup>2</sup>	25–29.9 kg/m <sup>2</sup>	<25 kg/m <sup>2</sup>
Children aged 2–19 y	>95th percentile	85th–95th percentile	<85th percentile
<b>Physical activity</b>			
Adults aged >20 y	None	1–149 min/wk moderate or 1–74 min/wk vigorous or 1–149 min/wk moderate+vigorous	150+ min/wk moderate or 75+ min/wk vigorous or 150+ min/wk moderate+vigorous
Children aged 12–19 y	None	>0 and <60 min of moderate or vigorous every day	60+ min of moderate or vigorous every day
<b>Healthy diet score</b>			
Adults aged >20 y	0–1 components	2–3 components	4–5 components
Children aged 5–19 y	0–1 components	2–3 components	4–5 components
<b>Total cholesterol</b>			
Adults aged >20 y	≥240 mg/dL	200–239 mg/dL or treated to goal	<200 mg/dL
Children aged 6–19 y	≥200 mg/dL	170–199 mg/dL	<170 mg/dL
<b>Blood pressure</b>			
Adults aged >20 y	SBP ≥140 or DBP ≥90 mm Hg	SBP 120–139 or DBP 80–89 mm Hg or treated to goal	<120/<80 mm Hg
Children aged 8–19 y	>95th percentile	90th–95th percentile or SBP ≥120 or DBP ≥80 mm Hg	<90th percentile
<b>Fasting plasma glucose</b>			
Adults aged >20 y	≥126 mg/dL	100–125 mg/dL or treated to goal	<100 mg/dL
Children aged 12–19 y	≥126 mg/dL	100–125 mg/dL	<100 mg/dL

... indicates no definition for this stratum; AHA, American Heart Association; BMI, body mass index; SBP, systolic blood pressure; DBP, diastolic blood pressure.

**Table 2-2. Prevalence of US Population With Ideal Cardiovascular Health and With Components of Ideal Cardiovascular Health, Overall and in Selected Age Strata From NHANES 2005–2006 (Baseline Available Data as of January 1, 2010)**

	Prevalence (%)				
	Ages 12–19 y	Ages 20+ y	Ages 20–39 y	Ages 40–59 y	Ages 60+ y
Ideal CV Health Profile (Composite–All 7)	0.0	0.0	0.0	0.0	0.0
Ideal Health Factors Index (Composite–All 4)	40.8	13.0	24.8	7.0	2.1
Individual components					
Total cholesterol <200 mg/dL (untreated)	72.4	46.6	65.2	38.0	28.5
SBP <120 and DBP <80 mm Hg (untreated)	79.7	41.7	62.8	35.8	15.1
Not current smoker (never or quit ≥12 mo)	82.9	72.2	65.1	72.3	84.5

Ideal Health Behaviors Index (Composite–All 4)	0.00	0.1	0.0	0.1	0.3
Individual components					
Physical activity at goal	44.0	45.2	51.3	43.8	37.0
Not current smoker (never or quit ≥12 mo)	82.9	72.2	65.1	72.3	84.5
BMI <25 kg/m <sup>2</sup>	64.8	33.2	39.9	28.6	29.3
4–5 diet goals met*	0.0	0.2	0.0	0.5	0.3
Fruits and vegetables ≥4.5 cups/d	7.1	12.1	9.4	10.7	18.9
Fish ≥2 3.5-oz servings/wk (preferably oily fish)	11.3	21.8	16.5	25.5	25.0
Sodium <1500 mg/d <sup>1</sup>	0.2	1.0	0.8	1.4	0.6
Sugar-sweetened beverages ≤450 kcal/wk	22.8	54.1	39.7	58.4	71.7
Whole grains (1.1 g fiber in 10 g carb) ≥3 1-oz-equivalent servings per day	2.7	6.2	5.5	6.1	7.6
Other dietary measures					
Nuts, legumes, seeds ≥4 servings/wk	9.7	20.8	17.7	23.6	21.7
Processed meats ≤2 servings/wk	48.6	52.5	50.9	53.1	54.1
Saturated fat <7% of total energy intake (kcal)	4.4	9.1	9.6	8.6	9.3

NHANES indicates National Health and Nutrition Examination Survey; CV, cardiovascular; SBP, systolic blood pressure; DBP, diastolic blood pressure; BMI, body mass index.

\*Scaled for 2000 kcal/d, and in the context of intake with appropriate energy balance and a DASH-like eating plan.

Estimates for adults aged 20+ years are standardized to the US 2000 standard population.

**Table 2-3. Selected Secondary Metrics for Monitoring Cardiovascular Disease, NHANES 1999–2006**

	N	Prevalence (%)	Standard Error
Prevalence of CVD (Self-reported)	16 786		
Coronary heart disease		3.62	0.16
Stroke		2.71	0.15
Congestive heart failure		2.42	0.12
Acute MI heart attack		3.61	0.20
Any self-reported history of CVD		8.13	0.28
Risk factor control in the presence of CVD	1728		
Current smoker or smokers who quit <12 mo ago	1723	36.53	2.66
Hypertension			
Prevalence of BP >140/90 mm Hg or taking medications	1596	40.56	2.35
Awareness among hypertensives	1129	84.97	4.39
Treatment among hypertensives	1129	79.63	4.37
BP control among treated	936	68.08	4.81
Hypercholesterolemia			
Prevalence of total cholesterol $\geq$ 240 mg/dL or taking medications	1581	37.28	2.40
Awareness among hypercholesterolemia	806	68.53	4.32
Treatment among hypercholesterolemia	806	59.15	4.47
Cholesterol control among treated	639	80.09	6.57
Overweight or Obese BMI $\geq$ 25.0 kg/m <sup>2</sup>	1625	78.10	2.91
Obese BMI $\geq$ 30.0 kg/m <sup>2</sup>		45.35	3.63
Diabetes mellitus			
Prevalence of fasting glucose $\geq$ 125 mg/dL or taking meds	1028	17.59	22.81
Awareness among diabetics	502	56.35	5.39
Treatment among diabetics	502	36.52	5.48
Blood glucose control among treated	182	27.55	4.68
Physical activity: intermediate or poor	1728	68.59	2.88
Moderate <150 min/wk AND			
Vigorous <75 min/wk AND			
Combined <150 min/wk			
Physical activity: none		44.99	3.44
Diet: intermediate or poor (2005–2006)	430		
Total diet score 0–3	365	100.00	0.00
Total diet score 0–1		80.80	4.69

NHANES indicates National Health and Nutrition Examination Survey; CVD, cardiovascular disease; MI, myocardial infarction; BP, blood pressure; BMI, body mass index.

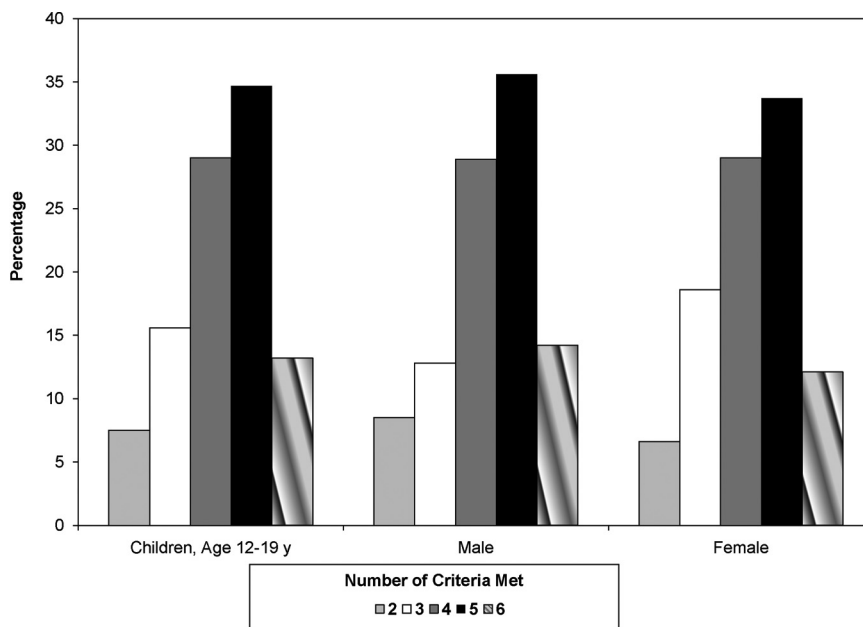

**Chart 2-1.** Prevalence (unadjusted) estimates for poor, intermediate, and ideal cardiovascular health for each of the 7 metrics of cardiovascular health in the American Heart Association 2020 goals, US children aged 12 to 19 years, National Health and Nutrition Examination Survey (NHANES) 2005–2006 (baseline available data as of January 1, 2010).

**Chart 2-2.** Age-standardized prevalence estimates for poor, intermediate, and ideal cardiovascular health for each of the 7 metrics of cardiovascular health in the American Heart Association 2020 goals, among US adults aged >20 years, National Health and Nutrition Examination Survey (NHANES) 2005–2006 (baseline available data as of January 1, 2010).

**Chart 2-3.** Proportion (unadjusted) of US children meeting different numbers of criteria for Ideal Cardiovascular Health, overall and by sex, National Health and Nutrition Examination Survey (NHANES) 2005–2006 (baseline available data as of January 1, 2010).

**Chart 2-4.** Age-standardized prevalence estimates of US adults meeting different numbers of criteria for Ideal Cardiovascular Health, overall and by age and sex subgroups, National Health and Nutrition Examination Survey (NHANES) 2005–2006 (baseline available data as of January 1, 2010).

**Chart 2-5.** Age-standardized prevalence estimates of US adults meeting different numbers of criteria for Ideal Cardiovascular Health, overall and in selected race subgroups from National Health and Nutrition Examination Survey (NHANES) 2005–2006 (baseline available data as of January 1, 2010).

**Chart 2-6.** Prevalence estimates of meeting at least 5 criteria for Ideal Cardiovascular Health, US adults (age-standardized), overall and by sex and race, and US children (unadjusted), by sex, National Health and Nutrition Examination Survey (NHANES) 2005–2006 (baseline available data as of January 1, 2010).

### 3. Cardiovascular Diseases

ICD-9 390–459, 745–747, ICD-10 I00–I99, Q20–Q28; see Glossary (Chapter 24) for details and definitions. See Tables 3-1 through 3-4 and Charts 3-1 through 3-21.

#### Abbreviations Used in Chapter 3

AED	automated external defibrillator
AHA	American Heart Association
AHRQ	Agency for Healthcare Research and Quality
AIDS	acquired immune deficiency syndrome
AP	angina pectoris
ARIC	Atherosclerosis Risk in Communities study
BMI	body mass index
BP	blood pressure
BRFSS	Behavioral Risk Factor Surveillance System
CABG	cardiac revascularization (coronary artery bypass graft)
CARDIA	Coronary Artery Risk Development in Young Adults
CDC	Centers for Disease Control and Prevention
CHD	coronary heart disease
CHF	congestive heart failure
CHS	Cardiovascular Health Study
CLRD	chronic lower respiratory disease
CPR	cardiopulmonary resuscitation
CVD	cardiovascular disease
DM	diabetes mellitus
ED	emergency department
EMS	emergency medical services
FHS	Framingham Heart Study
HBP	high blood pressure
HD	heart disease
HF	heart failure
HIV	human immunodeficiency virus
ICD-9	International Classification of Diseases, 9th Revision
ICD-10	International Classification of Diseases, 10th Revision
LDL	low-density lipoprotein
MEPS	Medical Expenditure Panel Survey
MESA	Multi-Ethnic Study of Atherosclerosis
MI	myocardial infarction
NAMCS	National Ambulatory Medical Care Survey
NCHS	National Center for Health Statistics
NHAMCS	National Hospital Ambulatory Medical Care Survey
NHANES	National Health and Nutrition Examination Survey
NHDS	National Hospital Discharge Survey
NHES	National Health Examination Survey
NHIS	National Health Interview Survey
NHHCS	National Home and Hospice Care Survey
NHLBI	National Heart, Lung, and Blood Institute
NIS	National Inpatient Sample
NNHS	National Nursing Home Survey
OPD	outpatient department
PA	physical activity
ROC	Resuscitation Outcomes Consortium
RR	relative risk
VF	ventricular fibrillation
VT	ventricular tachycardia

#### Prevalence

An estimated 82 600 000 American adults (>1 in 3) have 1 or more types of CVD. Of these, 40 400 000 are estimated to be  $\geq 60$  years of age. Total CVD includes diseases listed in the bullet points below, with the exception of congenital CVD. Because of overlap, it is not possible to add these conditions to arrive at a total.

- High blood pressure (HBP)—76 400 000 (defined as systolic pressure  $\geq 140$  mm Hg and/or diastolic pressure  $\geq 90$  mm Hg, use of antihypertensive medication, or being told at least twice by a physician or other health professional that one has HBP).
- Coronary heart disease (CHD)—16 300 000
  - MI (heart attack)— 7 900 000
  - AP (chest pain)— 9 000 000
- HF—5 700 000
- Stroke— 7 000 000
- Congenital cardiovascular defects— 650 000 to 1 300 000

The following age-adjusted prevalence estimates from the NHIS, NCHS are for diagnosed conditions for people  $\geq 18$  years of age in 2009<sup>1</sup>:

- Among whites only, 11.9% have heart disease (HD), 6.4% have CHD, 23.0% have hypertension, and 2.5% have had a stroke.
- Among blacks or African Americans, 11.2% have HD, 6.7% have CHD, 32.2% have hypertension, and 3.8% have had a stroke.
- Among Hispanics or Latinos, 8.5% have HD, 5.8% have CHD, 21.5% have hypertension, and 2.0% have had a stroke.
- Among Asians, 6.3% have HD, 3.9% have CHD, 19.4% have hypertension, and 1.3% have had a stroke.
- Among American Indians or Alaska Natives, 8.0% have HD, 4.1% (figure considered unreliable) have CHD, and 21.8% have hypertension. An estimate for stroke is not reported because of its large relative standard error.
- Among Native Hawaiians or other Pacific Islanders, HD, CHD, and stroke numbers are not reported because of large relative standard errors; 22.0% have hypertension, but the figure is considered unreliable.
- Asian Indian adults (9%) are  $\approx 2$ -fold more likely than Korean adults (4%) to have ever been told they have HD, based on data for 2004 to 2006.<sup>2</sup>

#### Incidence

- On the basis of the NHLBI's FHS original and offspring cohort data from 1980 to 2003<sup>3</sup>:
  - The average annual rates of first cardiovascular events rise from 3 per 1000 men at 35 to 44 years of age to 74 per 1000 men at 85 to 94 years of age. For women, comparable rates occur 10 years later in life. The gap narrows with advancing age.
  - Before 75 years of age, a higher proportion of CVD events due to CHD occur in men than in women, and a higher proportion of events due to stroke occur in women than in men.

- Among American Indian men 45 to 74 years of age, the incidence of CVD ranges from 15 to 28 per 1000 population. Among women, it ranges from 9 to 15 per 1000.<sup>4</sup>
- Data from the FHS indicate that the subsequent lifetime risk for all CVD in recipients starting free of known disease is 2 in 3 for men and >1 in 2 for women at 40 years of age (personal communication, Donald Lloyd-Jones, MD, Northwestern University, Chicago, Ill) (see Table 3-4).
- Analysis of FHS data among participants free of CVD at 50 years of age showed the lifetime risk for developing CVD was 51.7% for men and 39.2% for women. Median overall survival was 30 years for men and 36 years for women.<sup>5</sup>

## Mortality

*ICD-10 I00–I99, Q20–Q28 for CVD (CVD mortality includes congenital cardiovascular defects); C00–C97 for cancer; C33–C34 for lung cancer; C50 for breast cancer; J40–J47 for chronic lower respiratory disease (CLRD); G30 for Alzheimer disease; E10–E14 for diabetes mellitus (DM); and V01–X59, Y85–Y86 for accidents.*

- Mortality data show that CVD (I00–I99, Q20–Q28) as the underlying cause of death (including congenital cardiovascular defects) accounted for 33.6% (813 804) of all 2 423 712 deaths in 2007, or 1 of every 3 deaths in the United States. CVD any-mentions (1 342 314 deaths in 2007) constituted 55.4% of all deaths that year (NHLBI; NCHS public-use data files).<sup>6</sup> The 2007 death rate was 251.2 (excluding congenital cardiovascular defects) (NCHS).<sup>6</sup> In every year since 1900 except 1918, CVD accounted for more deaths than any other major cause of death in the United States.<sup>7–10</sup>
- On average, >2200 Americans die of CVD each day, an average of 1 death every 39 seconds. CVD claims more lives each year than cancer, CLRD, and accidents combined.<sup>6</sup>
- The 2007 overall death rate due to CVD (I00–I99) was 251.2. The rates were 294.0 for white males, 405.9 for black males, 205.7 for white females, and 286.1 for black females. From 1997 to 2007, death rates due to CVD (ICD-10 I00–I99) declined 27.8%. In the same 10-year period, the actual number of CVD deaths per year declined 14.2% (NHLBI tabulation).<sup>6</sup> (Appropriate comparability ratios were applied.)
- Among other causes of death in 2007, cancer caused 562 875 deaths; accidents, 123 706; Alzheimer disease, 74 632; and HIV/AIDS, 11 295.<sup>6</sup>
- The 2007 CVD (I00–I99) death rates were 300.3 for males and 211.6 for females. Death rates for cancer (malignant neoplasms) were 217.5 for males and 151.3 for females. Breast cancer claimed the lives of 40 599 females in 2007; lung cancer claimed 70 388. Death rates for females were 22.9 for breast cancer and 40.0 for lung cancer. One in 30 deaths in females was due to breast cancer, whereas 1 in 6.4 was due to CHD. For comparison, 1 in 4.5 females died of cancer, whereas 1 in 2.9 died of CVD (I00–I99, Q20–Q28). On the basis of 2007 mortality data, CVD caused ≈1 death per minute among females, or 421 918 deaths in

- females in 2007. That represents more female lives than were claimed by cancer, CLRD, Alzheimer disease, and accidents combined (unpublished NHLBI tabulation).<sup>6</sup>
- More than 150 000 Americans died of CVD (I00–I99) in 2007 who were <65 years of age, and nearly 33% of deaths owing to CVD occurred before the age of 75 years, which is well before the average life expectancy of 77.9 years.<sup>6</sup>
- In 2007, death rates for diseases of the heart in American Indians or Alaska Natives were 159.8 for males and 99.8 for females; for Asians or Pacific Islanders, they were 126.0 for males and 82.0 for females; and for Hispanics or Latinos, they were 165.0 for males and 111.8 for females.<sup>7</sup>
- According to the NCHS, if all forms of major CVD were eliminated, life expectancy would rise by almost 7 years. If all forms of cancer were eliminated, the estimated gain would be 3 years. According to the same study, the probability at birth of eventually dying of major CVD (I00–I78) is 47%, and the chance of dying of cancer is 22%. Additional probabilities are 3% for accidents, 2% for DM, and 0.7% for HIV.<sup>11</sup>
- In 2007, the leading causes of death in women ≥65 years of age were diseases of the heart (No. 1), cancer (No. 2), stroke (No. 3), and CLRD (No. 4). In older men, they were diseases of the heart (No. 1), cancer (No. 2), CLRD (No. 3), and stroke (No. 4).<sup>6,10</sup>
- A study of the decrease in US deaths due to CHD from 1980 to 2000 suggests that ≈47% of the decrease was attributable to increased use of evidence-based medical therapies and 44% to changes in risk factors in the population due to lifestyle and environmental changes.<sup>12</sup>
- Analysis of data from NCHS was used to determine the number of disease-specific deaths attributable to all non-optimal levels of each risk factor exposure, by age and sex. In 2005, tobacco smoking and high BP were estimated to be responsible for 467 000 deaths, accounting for ≈1 in 5 or 6 deaths among US adults. Overweight/obesity and physical inactivity were each estimated to be responsible for nearly 1 in 10 deaths. High dietary salt, low dietary omega-3 fatty acids, and high dietary trans fatty acids were the dietary risks with the largest estimated mortality effects.<sup>13</sup>

## Aftermath

- Among an estimated 45 million people with functional disabilities in the United States, HD, stroke, and hypertension are among the 15 leading conditions that caused those disabilities. Disabilities were defined as difficulty with activities of daily living or instrumental activities of daily living, specific functional limitations (except vision, hearing, or speech), and limitation in ability to do housework or work at a job or business.<sup>14</sup>

## Out-of-Hospital Cardiac Arrest

There is a wide variation in the reported incidence of and outcome for out-of-hospital cardiac arrest. These differences are due in part to differences in definition and ascertainment of cardiac arrest data, as well as differences in treatment after the onset of cardiac arrest. Cardiac arrest is defined as

cessation of cardiac mechanical activity and is confirmed by the absence of signs of circulation.<sup>15</sup>

- Extrapolation of the mortality rate observed in the Resuscitation Outcomes Consortium (ROC) to the total population of the United States suggests that each year, there are 295 000 (quasi confidence intervals 236 000 to 325 000) emergency medical services (EMS)-assessed out-of-hospital cardiac arrests in the United States.<sup>16</sup>
- ≈60% of out-of-hospital cardiac deaths are treated by EMS personnel.<sup>17</sup>
- Only 33% of those with EMS-treated out-of-hospital cardiac arrest have symptoms within 1 hour of death.<sup>18</sup>
- Among EMS-treated out-of-hospital cardiac arrests, 23% have an initial rhythm of ventricular fibrillation (VF), ventricular tachycardia (VT), or are shockable by automated external defibrillator (AED); 31% receive bystander cardiopulmonary resuscitation (CPR).<sup>16</sup>
- The incidence of cardiac arrest with an initial rhythm of VF is decreasing over time; however, the incidence of cardiac arrest with any initial rhythm is not decreasing.<sup>19</sup>
- Among ROC sites between December 2005 and May 2007, 32.0% of out-of-hospital cardiac arrests received lay-responder CPR and only 2.1% had an AED applied before EMS arrival. Overall chance of surviving until hospital discharge was 7%, and AED application was associated with a moderately increased odds of survival.<sup>20</sup>
- If bystander CPR is not provided, a sudden cardiac arrest victim's chances of survival fall 7% to 10% for every minute of delay until defibrillation.<sup>21–25</sup>
- The median survival rate to hospital discharge after EMS-treated out-of-hospital cardiac arrest with any first recorded rhythm is 7.9%.<sup>16</sup>
- The median survival rate after VF is 21%.<sup>16</sup>
- Extrapolation of data from ARIC, CHS, and Framingham suggests that there are 125 000 CHD deaths within 1 hour of symptom onset (NHLBI, written communication, July 13, 2010).
- A study conducted in New York City found the age-adjusted incidence of out-of-hospital cardiac arrest per 10 000 adults was 10.1 among blacks, 6.5 among Hispanics, and 5.8 among whites. The age-adjusted survival to 30 days after discharge was more than twice as poor for blacks as for whites, and survival among Hispanics was also lower than among whites.<sup>26</sup>
- In a systematic review of literature through 2008, the factors most correlated with survival to hospital discharge following out-of-hospital cardiac arrest were witness by a bystander, witness by EMS, receipt of bystander CPR, being found in VF or VT, and achieving return of spontaneous circulation.<sup>27</sup>

### Out-of-Hospital Cardiac Arrest: Children

- The reported incidence of out-of-hospital pediatric cardiac arrest varies widely (≈8 per 100 000).<sup>28</sup>
- There are >74 million individuals <18 years of age in the United States<sup>29</sup>; this implies that there are about 5920 pediatric out-of-hospital cardiac arrests annually of all

causes (including trauma, sudden infant death syndrome, respiratory causes, cardiovascular causes, and submersion).

- Thirty-five percent of EMS-treated pediatric cardiac arrest patients had an initial rhythm of VF, VT, or were shockable by AED; 35% received bystander CPR.<sup>28</sup>
- Studies that document voluntary reports of deaths among high school athletes suggest that the incidence of out-of-hospital cardiac arrest ranges from 0.28 to 1.0 deaths per 100 000 high school athletes annually nationwide.<sup>30,31</sup> Although incomplete, these numbers provide a basis for estimating the number of deaths in this age range.
- One report describes the incidence of nontraumatic pediatric cardiac arrest (among students 3 to 18 years of age) that occurs in schools and estimates rates (per 100 000 person-school-years) for elementary, middle, and high schools to be 0.18, 0.19, and 0.15, respectively, for the geographic area (King County, WA) and time frame (January 1, 1990, to December 31, 2005) studied.<sup>32</sup>
- The reported average rate of survival to hospital discharge after pediatric out-of-hospital cardiac arrest is 6%.
- Most sudden deaths in athletes were attributable to CVD (56%). Of the cardiovascular deaths that occurred, 29% occurred in blacks, 54% in high school students, and 82% with physical exertion during competition/training, and only 11% occurred in females, although this proportion has increased over time.<sup>33</sup>

### In-Hospital Cardiac Arrest

- A total of 287 facilities reported 18 817 events to the National Registry for Cardiopulmonary Resuscitation during 2009.
  - The rates of survival to discharge after in-hospital cardiac arrest were 33% among children and 21% among adults. Of these, 95% were monitored or witnessed.
  - Eighteen percent had VF or pulseless VT as the first recorded rhythm. Of these, 43% survived to discharge.

### Awareness of CPR

- Seventy-nine percent of the lay public are confident that they know what actions to take in a medical emergency; 98% recognize an AED as something that administers an electric shock to restore a normal heart beat among victims of sudden cardiac arrest; and 60% are familiar with CPR (Harris Interactive survey conducted on behalf of the AHA among 1132 US residents 18 years of age and older, January 8, 2008, through January 21, 2008).

### Awareness of Warning Signs and Risk Factors for CVD

- Surveys conducted by the AHA in 1997, 2000, 2003, and 2006 to evaluate trends in women's awareness, knowledge, and perceptions related to CVD found that, in 2006, awareness of HD as the leading cause of death among women was 57%, significantly higher than in prior surveys. Awareness was lower among black and Hispanic women

than among white women, and the racial/ethnic difference has not changed appreciably over time. In 2006, more than twice as many women felt uninformed about stroke compared with HD. Hispanic women were more likely than white women to report that there is nothing they can do to keep themselves from getting CVD. The majority of respondents reported confusion related to basic CVD prevention strategies.<sup>34</sup>

- A nationally representative sample of women responded to a questionnaire about history of CVD risk factors, self-reported actions taken to reduce risk, and barriers to heart health. According to the study, published in 2006, the rate of awareness of CVD as the leading cause of death had nearly doubled since 1997, was significantly greater for whites than for blacks and Hispanics, and was independently correlated with increased physical activity (PA) and weight loss in the previous year. Fewer than half of the respondents were aware of healthy levels of risk factors. Awareness that their personal level was not healthy was positively associated with preventive action. Most women took steps to lower risk in family members and themselves.<sup>35</sup>
- A total of 875 students in 4 Michigan high schools were given a survey to obtain data on the perception of risk factors and other knowledge-based assessment questions about CVD. Accidents were rated as the greatest perceived lifetime health risk (39%). Nearly 17% selected CVD as the greatest lifetime risk, which made it the third most popular choice after accidents and cancer. When asked to identify the greatest cause of death for each sex, 42% correctly recognized CVD for men, and 14% correctly recognized CVD for women; 40% incorrectly chose abuse/use behavior with a substance other than cigarettes as the most important CVD risk behavior.<sup>36</sup>

### Risk Factors

- Data from the 2003 CDC BRFSS survey of adults  $\geq 18$  years of age showed the prevalence of respondents who reported having  $\geq 2$  risk factors for HD and stroke was successively higher at higher age groups. The prevalence of having  $\geq 2$  risk factors was highest among blacks (48.7%) and American Indians/Alaska Natives (46.7%) and lowest among Asians (25.9%); prevalence was similar in women (36.4%) and men (37.8%). The prevalence of multiple risk factors ranged from 25.9% among college graduates to 52.5% among those with less than a high school diploma (or its equivalent). People reporting household income of  $\geq \$50\,000$  had the lowest prevalence (28.8%), and those reporting household income of  $\$10\,000$  had the highest prevalence (52.5%). Adults who reported being unable to work had the highest prevalence (69.3%) of  $\geq 2$  risk factors, followed by retired people (45.1%), unemployed adults (43.4%), homemakers (34.3%), and employed people (34.0%). Prevalence of  $\geq 2$  risk factors varied by state/territory and ranged from 27.0% (Hawaii) to 46.2% (Kentucky). Twelve states and 2 territories had a multiple-risk-factor prevalence of  $\geq 40\%$ : Alabama, Arkansas, Georgia, Indiana, Kentucky, Louisiana, Mississippi, North

Carolina, Ohio, Oklahoma, Tennessee, West Virginia, Guam, and Puerto Rico.<sup>37</sup>

- Data from the Chicago Heart Association Detection Project (1967 to 1973, with an average follow-up of 31 years) showed that in younger women (18 to 39 years of age) with favorable levels for all 5 major risk factors (BP, serum cholesterol, body mass index [BMI], DM, and smoking), future incidence of CHD and CVD is rare, and long-term and all-cause mortality are much lower than for those who have unfavorable or elevated risk factor levels at young ages. Similar findings applied to men in this study.<sup>38,39</sup>
- Analysis of several data sets by the CDC showed that in adults  $\geq 18$  years of age, disparities were common in all risk factors examined. In men, the highest prevalence of obesity (29.7%) was found in Mexican Americans who had completed a high school education. Black women with or without a high school education had a high prevalence of obesity (48.4%). Hypertension prevalence was high among blacks (41.2%) regardless of sex or educational status. Hypercholesterolemia was high among white and Mexican American men and white women regardless of educational status. CHD and stroke were inversely related to education, income, and poverty status. Hospitalization for total HD and acute MI was greater among men, but hospitalization for congestive heart failure (CHF) and stroke was greater among women. Among Medicare enrollees, CHF hospitalization was higher in blacks, Hispanics, and American Indians/Alaska Natives than among whites, and stroke hospitalization was highest in blacks. Hospitalizations for CHF and stroke were highest in the southeastern United States. Life expectancy remains higher in women than in men and in whites than in blacks by  $\approx 5$  years. CVD mortality at all ages tended to be highest in blacks.<sup>40</sup>
- Analysis of 5 cross-sectional, nationally representative surveys from the National Health Examination Survey (NHES) 1960–1962 to the NHANES 1999–2000 showed that the prevalence of key risk factors (ie, high cholesterol, HBP, current smoking, and total DM) decreased over time across all BMI groups, with the greatest reductions observed among overweight and obese groups. Total DM prevalence was stable within BMI groups over time; however, the trend has leveled off or been reversed for some of the risk factors in more recent years.<sup>41</sup>
- Data from BRFSS 2006–2008 demonstrated that during this 3-year period, 25.6% of non-Hispanic blacks, non-Hispanic whites, and Hispanics were obese, but prevalent obesity varied across groups: 35.7% for non-Hispanic blacks, 28.7% for Hispanics, and 23.7% for non-Hispanic whites.
- Data from NHANES 2005–2006 showed that only 9.6% of US adults met their recommended target of daily dietary sodium intake.<sup>42</sup>
- Analysis of  $>14\,000$  middle-aged subjects in the ARIC study sponsored by the NHLBI showed that  $>90\%$  of CVD events in black subjects, compared with  $\approx 70\%$  in white subjects, appeared to be explained by elevated or borderline risk factors. Furthermore, the prevalence of participants with elevated risk factors was higher in black subjects; after accounting for education and known CVD risk factors, the incidence of CVD was identical in black

and white subjects. Thus, the observed higher CVD incidence rate in black subjects appears to be largely attributable to a greater prevalence of elevated risk factors. These results suggest that the primary prevention of elevated risk factors might substantially impact the future incidence of CVD, and these beneficial effects would likely be applicable not only for white but also for black subjects.<sup>43</sup>

- Data from the MEPS 2004 Full-Year Data File showed that nearly 26 million US adults  $\geq 18$  years of age were told by a doctor that they had HD, stroke, or any other heart-related disease<sup>44</sup>:

- 56.6% of those surveyed said they engaged in moderate-to-vigorous PA 3 times per week; 57.9% of those surveyed who had not been told they had HD engaged in regular PA, more than those who had been told they had HD (46.3%).

- 38.6% maintained a healthy weight. Among those told that they had HD, 33.9% had a healthy weight compared with 39.3% who had never been told they had HD.

- 78.8% did not currently smoke. Among those ever told that they had indicators of HD, 18.3% continued to smoke.

- More than 93% engaged in at least 1 recommended behavior for prevention of HD: 75.5% engaged in 1 or 2; 18% engaged in all 3; and 6.5% did not engage in any of the recommended behaviors.

- Age-based variations:

- Moderate to vigorous PA  $\geq 3$  times per week varied according to age. Younger people (18 to 44 years of age) were more likely (59.9%) than those who were older (45 to 64 and  $\geq 65$  years of age, 55.3% and 48.5%, respectively) to engage in regular PA.

- A greater percentage of those 18 to 44 years of age had a healthy weight (43.7%) than did those 45 to 64 years of age and  $\geq 65$  years of age (31.4% and 37.3%, respectively).

- People  $\geq 65$  years of age were more likely to be current nonsmokers (89.7%) than were people 18 to 44 years of age and 45 to 64 years of age (76.1% and 77.7%, respectively).

- Race/ethnicity-based variations:

- Non-Hispanic whites were more likely than Hispanics or non-Hispanic blacks to engage in moderate-to-vigorous PA (58.5% versus 51.4% and 52.5%, respectively).

- Non-Hispanic whites were more likely to have maintained a healthy weight than were Hispanics or non-Hispanic blacks (39.8% versus 32.1% and 29.7%, respectively).

- Hispanics were more likely to be nonsmokers (84.2%) than were non-Hispanic whites and non-Hispanic blacks (77.8% and 76.3%, respectively).

- Sex-based variations:

- Men were more likely to have engaged in moderate-to-vigorous PA  $\geq 3$  times per week than women (60.3% versus 53.1%, respectively).

- Women were more likely than men to have maintained a healthy weight (45.1% versus 31.7%, respectively).

- 81.7% of women did not currently smoke, compared with 75.7% of men.

- Variations based on education level:

- A greater percentage of adults with at least some college education engaged in moderate-to-vigorous PA  $\geq 3$  times per week (60.8%) than did those with a high school education or less than a high school education (55.3% and 48.3%, respectively).

- A greater percentage of adults with at least some college education had a healthy weight (41.2%) than did those with a high school or less than high school education (36.2% and 36.1%, respectively).

- There was a greater percentage of nonsmokers among those with a college education (85.5%) than among those with a high school or less than high school education (73.8% and 69.9%, respectively).

- Participants (18 to 64 years of age at baseline) in the Chicago Heart Association Detection Project in Industry without a history of MI were investigated to determine whether traditional CVD risk factors were similarly associated with CVD mortality in black and white men and women. In general, the magnitude and direction of associations were similar by race. Most traditional risk factors demonstrated similar associations with mortality in black and white adults of the same sex. Small differences were primarily in the strength and not the direction of the association.<sup>45</sup>

- A study of nearly 1500 participants in the Multi-Ethnic Study of Atherosclerosis (MESA) study found that Hispanics with hypertension, hypercholesterolemia, and/or DM who speak Spanish at home and/or have spent less than half a year in the United States have higher systolic BP, low-density lipoprotein (LDL) cholesterol, and fasting blood glucose, respectively, than Hispanics who speak English and who have lived a longer period of time in the United States.<sup>46</sup>

### Family History of Premature-Onset CVD

- There is consistent evidence from multiple large-scale prospective epidemiology studies for a strong and significant association of a reported family history of premature parental CHD with incident MI or CHD in offspring. In the FHS, the occurrence of a validated premature atherosclerotic CVD event in either a parent<sup>47</sup> or a sibling<sup>48</sup> was associated with an  $\approx 2$ -fold elevated risk for CVD, independent of other traditional risk factors.

- Addition of family history of premature CVD to a model that contained traditional risk factors provided modestly improved prognostic value in the FHS.<sup>47</sup> Family history of premature MI is also an independent risk factor in other multivariable risk models that contain traditional risk factors in large cohorts of women<sup>50</sup> and men.<sup>50</sup>

- Parental history of premature CHD is associated with increased burden of atherosclerosis in the coronary arteries and the abdominal aorta.<sup>51,52</sup>
- In the FHS, a parental history of validated HF is associated with a 1.7-fold higher risk of HF in offspring, after multivariable adjustment.<sup>53</sup>
- A family history of early-onset sudden cardiac death in a first-degree relative is associated with a >2-fold higher risk for sudden cardiac death in offspring on the basis of available case-control studies.<sup>54</sup>
- The 2004 HealthStyles survey of 4345 people in the United States indicated that most respondents believe that knowing their family history is important for their own health, but few are aware of the specific health information from relatives necessary to develop a family history.<sup>55</sup>
- An accurate and complete family history may identify rare mendelian conditions such as hypertrophic cardiomyopathy, long-QT syndrome, or familial hypercholesterolemia. However, in most people with a family history of a CVD event, a known rare mendelian condition is not identified.
- Studies are under way to determine genetic variants that may help identify people at increased risk of CVD.

### Impact of Healthy Lifestyle and Low Risk Factor Levels

Much of the literature on CVD has focused on factors associated with increasing risk for CVD and on factors associated with poorer outcomes in the presence of CVD; however, in recent years, a number of studies have defined the potential beneficial effects of healthy lifestyle factors and lower CVD risk factor burden on CVD outcomes and longevity. These studies suggest that prevention of risk factor development at younger ages may be the key to “successful aging,” and they highlight the need for intensive prevention efforts at younger and middle ages once risk factors develop to increase the likelihood of healthy longevity.

- The lifetime risk for CVD and median survival were highly associated with risk factor presence and burden at 50 years of age among >7900 men and women from the FHS followed up for 111 000 person-years. In this study, optimal risk factor burden at 50 years of age was defined as BP <120/80 mm Hg, total cholesterol <180 mg/dL, absence of DM, and absence of smoking. Elevated risk factors were defined as stage 1 hypertension or borderline high cholesterol (200 to 239 mg/dL). Major risk factors were defined as stage 2 hypertension, elevated cholesterol ( $\geq 240$  mg/dL), current smoking, and DM. Remaining lifetime risks for atherosclerotic CVD events were only 5.2% in men and 8.2% in women with optimal risk factors at 50 years of age compared with 68.9% in men and 50.2% in women with  $\geq 2$  major risk factors at age 50. In addition, men and women with optimal risk factors had a median life expectancy  $\geq 10$  years longer than those with  $\geq 2$  major risk factors at age 50 years.<sup>5</sup>
- A recent study examined the association between low lifetime predicted risk for CVD (ie, having all optimal or near-optimal risk factor levels) and burden of subclinical atherosclerosis in younger adults in the Coronary Artery

Risk Development in Young Adults (CARDIA) and MESA studies of the NHLBI. Among participants <50 years of age, nearly half had low and half had high predicted lifetime risks for CVD. Those with low predicted lifetime risk had lower prevalence and less severe amounts of coronary calcification and less carotid intima-media thickening, even at these younger ages, than those with high predicted lifetime risk. During follow-up, those with low predicted lifetime risk also had less progression of coronary calcium.<sup>56</sup>

- In another study, FHS investigators followed up 2531 men and women who were examined between the ages of 40 and 50 years and observed their overall rates of survival and survival free of CVD to 85 years of age and beyond. Low levels of the major risk factors in middle age was associated with overall survival and morbidity-free survival to 85 years of age or more.<sup>57</sup>
  - Overall, 35.7% survived to the age of 85 years, and 22% survived to that age free of major morbidities.
  - Factors associated with survival to the age of 85 years included female sex, lower systolic BP, lower total cholesterol, better glucose tolerance, absence of current smoking, and higher level of education attained. Factors associated with survival to the age of 85 years free of MI, unstable angina, HF, stroke, dementia, and cancer were nearly identical.
  - When adverse levels of 4 of these factors were present in middle age, <5% of men and  $\approx 15\%$  of women survived to 85 years of age.
- A study of 366 000 men and women from the Multiple Risk Factor Intervention Trial (MRFIT) and Chicago Heart Association Detection Project in Industry defined low-risk status as follows: serum cholesterol level <200 mg/dL, untreated BP 120/80 mm Hg, absence of current smoking, absence of DM, and absence of major electrocardiographic abnormalities. Compared with those who did not have low risk factor burden, those with low risk factor burden had between 73% and 85% lower relative risk (RR) for CVD mortality, 40% to 60% lower relative total mortality rates, and 6 to 10 years' longer life expectancy.<sup>39</sup>
- A study of 84 129 women enrolled in the Nurses' Health Study identified 5 healthy lifestyle factors, including absence of current smoking, drinking half a glass or more of wine per day (or equivalent alcohol consumption), half an hour or more per day of moderate or vigorous PA, BMI <25 kg/m<sup>2</sup>, and dietary score in the top 40% (which included diets with lower amounts of trans fats, lower glycemic load, higher cereal fiber, higher marine omega-3 fatty acids, higher folate, and higher polyunsaturated to saturated fat ratio). When 3 of the 5 healthy lifestyle factors were present, the RR for CHD over a 14-year period was 57% lower; when 4 were present, RR was 66% lower; and when all 5 factors were present, RR was 83% lower.<sup>58</sup> However, data from NHANES 1999–2002 showed that only about one third of adults complied with 6 or more of the recommended heart-healthy behaviors. Dietary recom-

mentations, in general, and daily fruit intake recommendations, in particular, were least likely to be followed.<sup>59</sup>

- In the Chicago Heart Association Detection Project in Industry, remaining lifetime risks for CVD death were noted to increase substantially and in a graded fashion according to the number of risk factors present in middle age (40 to 59 years of age). However, remaining lifetime risks for non-CVD death also increased dramatically with increasing CVD risk factor burden. These data help to explain the markedly greater longevity experienced by those who reach middle age free of major CVD risk factors.<sup>60</sup>
- Among individuals 70 to 90 years of age, adherence to a Mediterranean-style diet and greater PA are associated with 65% to 73% relatively lower rates of all-cause mortality, as well as lower mortality rates due to CHD, CVD, and cancer.<sup>61</sup>
- Seventeen-year mortality data from the NHANES II Mortality Follow-Up Study indicated that the RR for fatal CHD was 51% lower for men and 71% lower for women with none of 3 major risk factors (hypertension, current smoking, and elevated total cholesterol [ $\geq 240$  mg/dL]) than for those with 1 or more risk factors. Had all 3 major risk factors not occurred, it is hypothesized that 64% of all CHD deaths among women and 45% of CHD deaths in men could have been avoided.<sup>62</sup>
- Investigators from the Chicago Heart Association Detection Project in Industry have also observed that risk factor burden in middle age is associated with better quality of life at follow-up in older age ( $\approx 25$  years later) and lower average annual Medicare costs at older ages.
  - The presence of a greater number of risk factors in middle age is associated with lower scores at older ages on assessment of social functioning, mental health, walking, and health perception in women, with similar findings in men.<sup>63</sup>
  - Similarly, the existence of a greater number of risk factors in middle age is associated with higher average annual CVD-related and total Medicare costs (once Medicare eligibility is attained).<sup>64</sup>

### Hospital Discharges, Ambulatory Care Visits, and Nursing Home Residents

- From 1997 to 2007, the number of inpatient discharges from short-stay hospitals with CVD as the first-listed diagnosis decreased from 6 097 000 to 5 890 000 (NHDS, NCHS, and NHLBI). In 2007, CVD ranked highest among all disease categories in hospital discharges. (NHDS, NCHS, and NHLBI).
- In 2008, there were 91 736 000 physician office visits with a primary diagnosis of CVD (NCHS, NAMCS).<sup>65</sup> In 2008, there were 4 866 000 ED visits with a primary diagnosis of CVD (NCHS, National Hospital Ambulatory Medical Care Survey [NHAMCS]).<sup>66</sup>
- In 2008, there were 8 795 000 hospital OPD visits with a primary diagnosis of CVD (NHAMCS).<sup>66</sup> In 2005,  $\approx 1$  of every 6 hospital stays, or almost 6 million, resulted

from CVD (AHRQ, NIS). The total inpatient hospital cost for CVD was \$71.2 billion, approximately one fourth of the total cost of inpatient hospital care in the United States. The average cost per hospitalization was  $\approx 41\%$  higher than the average cost for all stays. Hospital admissions that originated in the ED accounted for 60.7% of all hospital stays for CVD. This was 41% higher than the overall rate of 43.1%; 3.3% of patients admitted to the hospital for CVD died in the hospital, which was significantly higher than the average in-hospital death rate of 2.1%.<sup>67</sup>

- In 2004, coronary atherosclerosis was estimated to be responsible for 1.2 million hospital stays and was the most expensive condition treated. This condition resulted in  $> \$44$  billion in expenses. More than half of the hospital stays for coronary atherosclerosis were among patients who also received percutaneous coronary intervention or cardiac revascularization (coronary artery bypass graft; CABG) during their stay. Acute MI resulted in \$31 billion of inpatient hospital charges for 695 000 hospital stays. The 1.1 million hospitalizations for CHF amounted to nearly \$29 billion in hospital charges.<sup>68</sup>
- In 2003,  $\approx 48.3\%$  of inpatient hospital stays for CVD were for women, who accounted for 42.8% of the national cost (\$187 billion) associated with these conditions. Although only 40% of hospital stays for acute MI and coronary atherosclerosis were for women, more than half of all stays for nonspecific chest pain, CHF, and stroke were for women. There was no difference between men and women in hospitalizations for cardiac dysrhythmias.<sup>69</sup>
- Circulatory disorders were the most frequent reason for admission to the hospital through the ED, accounting for 26.3% of all admissions through the ED. After pneumonia, the most common heart-related conditions (in descending order) were CHF, chest pain, hardening of the arteries, and heart attack, which together accounted for  $> 15\%$  of all admissions through the ED. Stroke and irregular heart beat ranked seventh and eighth, respectively.<sup>70</sup>
- In 2004, nursing home residents had a primary diagnosis of CVD at admission (23.7%) and at the time of interview (25%). This was the leading primary diagnosis for these residents (NCHS, NNHS).<sup>67</sup>
- Among current home health care patients in 2007, 18.3% had a primary diagnosis of CVD at admission and 62.9% had any diagnosis of CVD at the time of interview (NCHS, National Home and Hospice Care Survey [NHHCS] unpublished data).
- Among patients discharged from hospice in 2007, 15.8% had a primary diagnosis of CVD at admission (NCHS, NHHCS unpublished data).

### Operations and Procedures

- In 2007, an estimated 6 846 000 inpatient cardiovascular operations and procedures were performed in the United States; 3.9 million were performed on males, and 2.9 million were performed on females (NHDS, NCHS, and NHLBI).

## Cost

- The estimated direct and indirect cost of CVD for 2007 is \$286.6 billion (MEPS, AHRQ, and NHLBI).
- In 2006, \$32.7 billion in program payments were made to Medicare beneficiaries discharged from short-stay hospitals with a principal diagnosis of CVD. That was an average of \$10 201 per discharge.<sup>71</sup>

**Table 3-1. Cardiovascular Disease**

Population Group	Prevalence, 2008 Age ≥20 y	Mortality, 2007 All Ages*	Hospital Discharges, 2007 All Ages	Cost, 2007
Both sexes	82 600 000 (36.2%)	813 804	5 890 000	\$286.6 Billion
Males	39 900 000 (37.4%)	391 886 (48.2%)†	3 016 000	...
Females	42 700 000 (35.0%)	421 918 (51.8%)†	2 874 000	...
NH white males	37.4%	334 589	...	...
NH white females	33.8%	362 762	...	...
NH black males	44.8%	47 387	...	...
NH black females	47.3%	50 015	...	...
Mexican American males	30.7%	...	...	...
Mexican American females	30.9%	...	...	...

Ellipses (. . .) indicate data not available; NH, non-Hispanic.

\*Mortality data are for whites and blacks and include Hispanics.

†These percentages represent the portion of total cardiovascular disease mortality that is attributable to males versus females.

Sources: Prevalence: National Health and Nutrition Examination Survey 2005–2008, National Center for Health Statistics (NCHS) and National Heart, Lung, and Blood Institute (NHLBI). Percentages for racial/ethnic groups are age-adjusted for Americans ≥20 years of age. Age-specific percentages are extrapolated to the 2008 US population estimates. Mortality: NCHS. These data represent underlying cause of death only. Data include congenital cardiovascular disease mortality. Hospital discharges: National Hospital Discharge Survey, NCHS. Data include those inpatients discharged alive, dead, or of unknown status. Cost: NHLBI. Data include estimated direct and indirect costs for 2007.

\*Cardiovascular disease (CVD) is defined here as International Classification of Diseases (ICD)-10 I00–I78.

†Coronary heart disease (CHD) is defined here as ICD-10 I20–I25.

‡Stroke is defined here as ICD-10 I60–I69.

§Rank is lowest to highest.

||Percentage changes for Puerto Rico are for 2000 to 2005–2007.

Source: Health Data Interactive, 2005–2007. Data provided by personal communication with National Heart, Lung, and Blood Institute.

The Agency for Healthcare Research and Quality has released state-level data for heart disease for all 50 states and the District of Columbia. The data are taken from the Congressionally mandated National Healthcare Quality Report (NHQR), available at <http://statesnapshots.ahrq.gov/snaps07/index.jsp>. In addition, the Women's Health and Mortality Chartbook of the National Center for Health Statistics has state-related data for women available at [http://www.cdc.gov/nchs/data/healthywomen/womenschartbook\\_aug2004.pdf](http://www.cdc.gov/nchs/data/healthywomen/womenschartbook_aug2004.pdf). Also, at <http://apps.nccd.cdc.gov/brfss-smart/index.asp>, Metropolitan/Micropolitan Area Risk (MMSA) data are available for 500 such areas nationwide. Behavioral Risk Factor Surveillance System data are also collected within each state (<http://www.cdc.gov/brfss>). The Centers for Disease Control and Prevention (CDC) has the Geographic Information Systems (GIS), which provides mortality rates down to the county level, by sex and ethnicity, available at <http://www.cdc.gov/gis/>. The 2008 Atlas of Stroke Hospitalizations Among Medicare Beneficiaries (CDC, 2008) is a new resource that provides data down to the county level, by sex and race (available at [http://www.cdc.gov/dhdsp/library/stroke\\_hospitalization\\_atlas.htm](http://www.cdc.gov/dhdsp/library/stroke_hospitalization_atlas.htm)).

Rates are adjusted to the European Standard population. For countries using International Classification of Diseases (ICD)-9, the ICD-9 codes are 390–459 for CVD, 410–414 for coronary heart disease (CHD), and 430–438 for stroke. ICD-10 codes are I00–I99 for cardiovascular disease (CVD), I20–I25 for CHD, and I60–I69 for stroke.

## 4. Subclinical Atherosclerosis

See Table 4-1 and Charts 4-1 through 4-6.

Atherosclerosis, a systemic disease process in which fatty deposits, inflammation, cells, and scar tissue build up within the walls of arteries, is the underlying cause of the majority of clinical cardiovascular events. Individuals who develop atherosclerosis tend to develop it in a number of different types of arteries (large and small arteries and those feeding the heart, brain, kidneys, and extremities), although they may have much more in some artery types than others. In recent decades, advances in imaging technology have allowed for improved ability to detect and quantify atherosclerosis at all stages and in multiple different vascular beds. Two modalities, computed tomography (CT) of the chest for evaluation of coronary artery calcification (CAC) and B-mode ultrasound of the neck for evaluation of carotid artery intima-media thickness (IMT), have been used in large studies with outcomes data and may help define the burden of atherosclerosis in individuals before they develop clinical events such as heart attack or stroke. Another commonly used method for detecting and quantifying atherosclerosis in the peripheral arteries is the ankle-brachial index, which is discussed in Chapter 10. Data on cardiovascular outcomes are starting to emerge for additional modalities for measuring subclinical disease, including brachial artery reactivity testing, aortic and

carotid magnetic resonance imaging (MRI), and tonometric methods of measuring vascular compliance or microvascular reactivity. Further research may help to define the role of these techniques in cardiovascular risk assessment. Some guidelines have recommended screening for subclinical atherosclerosis, especially by CAC, or IMT may be appropriate in people at intermediate risk for heart disease (eg, 10-year estimated risk of 10% to 20%) but not for lower-risk general population screening or for people with preexisting HD, DM, or other high-risk conditions.<sup>1,2</sup>

### Coronary Artery Calcification

#### Background

- CAC is a measure of the burden of atherosclerosis in the heart arteries and is measured by CT. Other parts of the atherosclerotic plaque, including fatty (eg, cholesterol-rich components) and fibrotic components, often accompany CAC and may be present even in the absence of CAC.
- The presence of any CAC, which indicates that at least some atherosclerotic plaque is present, is defined by an Agatston score >0. Clinically significant plaque, frequently an indication for more aggressive risk factor management, is often defined by a score  $\geq 100$  or a score  $\geq 75$ th percentile for one's age and sex. A score  $\geq 400$  has been noted to be an indication for further diagnostic evaluation (eg, exercise testing or myocardial perfusion imaging) for coronary artery disease (CAD).

#### Prevalence

- The NHLBI's FHS measured CAC in 3238 white adults from <45 years of age to  $\geq 75$  years of age.<sup>3</sup>
- Overall, 32.0% of women and 52.9% of men had prevalent CAC, defined as age-specific cut points >90th percentile in a healthy referent sample.
- Among FHS participants at intermediate risk, 58% of women and 64% of men had prevalent CAC.
- The NHLBI's Coronary Artery Risk Development in Young Adults (CARDIA) study measured CAC in 3043 black and white adults 33 to 45 years of age (at the CARDIA year 15 examination).<sup>4</sup>
  - Overall, 15.0% of men and 5.1% of women, 5.5% of those 33 to 39 years of age and 13.3% of those 40 to 45 years of age, had prevalent CAC. Overall, 1.6% of subjects had a score that exceeded 100.
  - Chart 4-1 shows the prevalence of CAC by ethnicity and sex. The prevalence of CAC was lower in black men than in white men but was similar in black and white women at these ages.
- The NHLBI's MESA study measured CAC in 6814 subjects 45 to 84 years of age, including white (n=2619), black (n=1898), Hispanic (n=1494), and Chinese (n=803) men and women.<sup>5</sup>
  - Chart 4-2 shows the prevalence of CAC by sex and ethnicity.
  - The prevalence and 75th percentile levels of CAC were highest in white men and lowest in black and Hispanic women. Significant ethnic differences persisted after

#### Abbreviations Used in Chapter 4

BMI	body mass index
BP	blood pressure
CAC	coronary artery calcification
CAD	coronary artery disease
CARDIA	Coronary Artery Risk Development in Young Adults
CHD	coronary heart disease
CHS	Cardiovascular Health Study
CT	computed tomography
CVD	cardiovascular disease
DBP	diastolic blood pressure
DM	diabetes mellitus
FHS	Framingham Heart Study
FMD	flow-mediated dilation
FRS	Framingham Risk Score
HDL	high-density lipoprotein
HD	heart disease
HR	hazard ratio
IMT	intima-media thickness
LDL	low-density lipoprotein
MESA	Multi-Ethnic Study of Atherosclerosis
mg/dL	milligrams per deciliter
MRI	magnetic resonance imaging
NHLBI	National Heart, Lung, and Blood Institute
RR	relative risk
SBP	systolic blood pressure
SD	standard deviation

adjustment for risk factors, with the RR of coronary calcium being 22% less in blacks, 15% less in Hispanics, and 8% less in Chinese than in whites.

- Table 4-1 shows the 75th percentile levels of CAC by sex and race at selected ages. These might be considered cut points above which more aggressive efforts to control risk factors (eg, elevated cholesterol or BP) could be implemented and/or at which treatment goals might be more aggressive (eg, LDL cholesterol <100 mg/dL instead of <130 mg/dL).

### **CAC and Incidence of Coronary Events**

- The NHLBI's MESA study recently reported on the association of CAC scores with first CHD events over a median follow-up of 3.9 years among a population-based sample of 6722 men and women (39% white, 27% black, 22% Hispanic, and 12% Chinese).<sup>6</sup>
  - Chart 4-3 shows the relative risks (RRs) or hazard ratios (HRs) associated with CAC scores of 1 to 100, 101 to 300, and >300 compared with those without CAC (score=0), after adjustment for standard risk factors. People with CAC scores of 1 to 100 had ≈4 times greater risk and those with CAC scores >100 were 7 to 10 times more likely to experience a coronary event than those without CAC.
  - CAC provided similar predictive value for coronary events in whites, Chinese, blacks, and Hispanics (HRs ranging from 1.15 to 1.39 for each doubling of coronary calcium).
- In another report of a community-based sample, not referred for clinical reasons, the South Bay Heart Watch examined CAC in 1461 adults (average age 66 years) with coronary risk factors, with a median of 7.0 years of follow-up.<sup>7</sup>
- Chart 4-4 shows the HRs associated with increasing CAC scores (relative to CAC=0 and <10% risk category) in low-risk (<10%), intermediate-risk (10% to 15% and 16% to 20%), and high-risk (>20%) Framingham Risk Score (FRS) categories of estimated risk for CHD in 10 years. Increasing CAC scores further predicted risk in intermediate- and high-risk groups.
- In a study of healthy adults 60 to 72 years of age who were free of clinical CAD, predictors of the progression of CAC were assessed. Predictors tested included age, sex, race/ethnicity, smoking status, BMI, family history of CAD, C-reactive protein, several measures of DM, insulin levels, BP, and lipids. Insulin resistance, in addition to the traditional cardiac risk factors, independently predicts progression of CAC.<sup>8</sup> Clinically, however, it is not yet recommended to conduct serial scanning of CAC to measure effects of therapeutic interventions.
- It is noteworthy that, as recently demonstrated in the MESA study in 5878 subjects with a median of 5.8 years of follow-up, the addition of CAC to standard risk factors resulted in significant improvement of classification of risk for incident CHD events, placing 77% of people in the highest or lowest risk categories compared with 69% based

on risk factors alone. Moreover, an additional 23% of those who experienced events were reclassified as high risk and 13% with events were reclassified as low risk.<sup>9</sup>

### **Carotid IMT**

#### **Background**

- Carotid IMT measures the thickness of 2 layers (the intima and media) of the wall of the carotid arteries, the largest conduits of blood going to the brain. Carotid IMT is thought to be an even earlier manifestation of atherosclerosis than CAC, because thickening precedes the development of frank atherosclerotic plaque. Carotid IMT methods are still being refined, so it is important to know which part of the artery was measured (common carotid, internal carotid, or bulb) and whether near and far walls were both measured. This information can affect the average-thickness measurement that is usually reported.
- Unlike CAC, everyone has some thickness to their arteries, but people who develop atherosclerosis have greater thickness. Ultrasound of the carotid arteries can also detect plaques and determine the degree of narrowing of the artery that they may cause. Epidemiological data, including the data discussed below, have indicated that high-risk levels might be considered as those in the highest quartile or quintile for one's age and sex, or  $\geq 1$  mm.
- Although ultrasound is commonly used to diagnose plaque in the carotid arteries in people who have had strokes or who have bruits (sounds of turbulence in the artery), guidelines are limited as to screening of asymptomatic people for carotid IMT to quantify atherosclerosis or predict risk. However, some organizations have recognized that carotid IMT measurement by B-mode ultrasonography may provide an independent assessment of coronary risk.<sup>10</sup>

#### **Prevalence and Association With Incident Cardiovascular Events**

- The Bogalusa Heart Study measured carotid IMT in 518 black and white men and women at a mean age of  $32 \pm 3$  years. These men and women were healthy but overweight.<sup>11</sup>
  - The mean values of carotid IMT for the different segments are shown in Chart 4-5 by sex and race. Men had significantly higher carotid IMT in all segments than women, and blacks had higher common carotid and carotid bulb IMTs than whites.
  - Even at this young age, after adjustment for age, race, and sex, carotid IMT was associated significantly and positively with waist circumference, SBP, DBP, and LDL cholesterol. Carotid IMT was inversely correlated with high-density lipoprotein (HDL) cholesterol levels. Participants with greater numbers of adverse risk factors (0, 1, 2, 3, or more) had stepwise increases in mean carotid IMT levels.
- In a subsequent analysis, the Bogalusa investigators examined the association of risk factors measured since childhood with carotid IMT measured in these young adults.<sup>12</sup>

Higher BMI and LDL cholesterol levels measured at 4 to 7 years of age were associated with increased risk for being >75th percentile for carotid IMT in young adulthood. Higher SBP and LDL cholesterol and lower HDL cholesterol in young adulthood were also associated with having high carotid IMT. These data highlight the importance of adverse risk factor levels in early childhood and young adulthood in the early development of atherosclerosis.

- Among both women and men in MESA, blacks had the highest common carotid IMT, but they were similar to whites and Hispanics in internal carotid IMT. Chinese participants had the lowest carotid IMT, in particular, in the internal carotid, of the 4 ethnic groups (Chart 4-6).
- The NHLBI's CHS reported follow-up of 4476 men and women  $\geq 65$  years of age (mean age 72 years) who were free of CVD at baseline.<sup>13</sup>
  - Mean maximal common carotid IMT was  $1.03 \pm 0.20$  mm, and mean internal carotid IMT was  $1.37 \pm 0.55$  mm.
  - After a mean follow-up of 6.2 years, those with maximal carotid IMT in the highest quintile had a 4- to 5-fold greater risk for incident heart attack or stroke than those in the bottom quintile. After adjustment for other risk factors, there was still a 2- to 3-fold greater risk for the top versus the bottom quintile.
- More recently, the Atherosclerosis Risk in Communities Study has demonstrated in 13 145 subjects the addition of carotid IMT combined with identification of plaque presence or absence to traditional risk factors to reclassify risk in 23% of individuals overall, with a net reclassification improvement of 9.9% (with most classified to a lower risk group). There was a modest, but statistically significant improvement in the area under the receiver-operator characteristic curve from 0.742 to 0.755.<sup>14</sup>

### CAC and Carotid IMT

- In the NHLBI's MESA study of white, black, Chinese, and Hispanic adults 45 to 84 years of age, carotid IMT and CAC were found to be commonly associated, but patterns of association differed somewhat by sex and race.<sup>15</sup>
  - Common and internal carotid IMT were greater in women and men who had CAC than in those who did not, regardless of ethnicity.
  - Overall, CAC prevalence and scores were associated with carotid IMT, but associations were somewhat weaker in blacks than in other ethnic groups.
  - In general, blacks had the thickest carotid IMT of all 4 ethnic groups, regardless of the presence of CAC.
  - Common carotid IMT differed little by race/ethnicity in women with any CAC, but among women with no CAC, IMT was higher among blacks (0.86 mm) than in the other 3 groups (0.76 to 0.80 mm).
- In a more recent analysis from the NHLBI's MESA study, the investigators reported on follow-up of 6698 men and

women in 4 ethnic groups over 5.3 years and compared the predictive utility of carotid IMT and CAC.<sup>16</sup>

- CAC was associated more strongly than carotid IMT with the risk of incident CVD.
- After adjustment for each other (CAC score and IMT) and for traditional CVD risk factors, the HR for CVD increased 2.1-fold for each 1-standard deviation (SD) increment of log-transformed CAC score versus 1.3-fold for each 1-SD increment of the maximum carotid IMT.
- For CHD events, the HRs per 1-SD increment increased 2.5-fold for CAC score and 1.2-fold for IMT.
- A receiver operating characteristic curve analysis also suggested that CAC score was a better predictor of incident CVD than was IMT, with areas under the curve of 0.81 versus 0.78, respectively.
- Investigators from the NHLBI's CARDIA and MESA studies examined the burden and progression of subclinical atherosclerosis among adults <50 years of age. Ten-year and lifetime risks for CVD were estimated for each participant, and the young adults were stratified into 3 groups: (1) those with low 10-year (<10%) and low lifetime (<39%) predicted risk for CVD; (2) those with low 10-year (<10%) but high lifetime ( $\geq 39\%$ ) predicted risk; and (3) those with high 10-year risk (>10%). The latter group had the highest burden and greatest progression of subclinical atherosclerosis. Given the young age of those studied,  $\approx 90\%$  of participants were at low 10-year risk, but of these, half had high predicted lifetime risk. Compared with those with low short-term/low lifetime predicted risks, those with low short-term/high lifetime predicted risk had significantly greater burden and progression of CAC and significantly greater burden of carotid IMT, even at these younger ages. These data confirm the importance of early exposure to risk factors for the onset and progression of subclinical atherosclerosis.<sup>17</sup>

### Measures of Vascular Function and Incident CVD Events

#### Background

- Measures of arterial tonometry (stiffness) are based on the concept that pulse pressure has shown to be an important risk factor for CVD. Arterial tonometry offers the ability to directly and noninvasively measure central pulse wave velocity in the thoracic and abdominal aorta.
- Brachial flow-mediated dilation (FMD) is a marker for nitric oxide release from the endothelium that can be measured using ultrasound. Impaired FMD is an early marker of CVD.
- Recommendations have not been specific, however, as to which, if any, measures of vascular function may be useful for CVD risk stratification in selected patient subgroups.

#### Arterial Tonometry and CVD

- The Rotterdam Study measured arterial stiffness in 2835 elderly participants (mean age 71 years<sup>18</sup>). They found that

as aortic pulse wave velocity increased, the risk of coronary heart disease was 1.72 (second versus first tertile) and 2.45 (third versus first tertile). Results remained robust even after accounting for carotid IMT, ankle-brachial index, and pulse pressure.

- A study from Denmark measured 1678 individuals aged 40 to 70 years, and found that aortic pulse wave velocity increased CVD risk by 16% to 20%.<sup>19</sup>
- The FHS measured several indices of arterial stiffness, including pulse wave velocity wave reflection and central pulse pressure.<sup>20</sup> They found that not only was higher pulse wave velocity associated with a 48% increased risk of incident CVD events, but pulse wave velocity additionally improved CVD risk prediction (integrated discrimination index of 0.7%,  $P < 0.05$ ).

#### Flow-Mediated Dilatation and CVD

- The MESA study measured FMD in 3026 participants (mean age 61 years) that were free of CVD. As FMD increased (ie, improved brachial function), the risk of CVD was 16% lower.<sup>21</sup> FMD also improved CVD risk prediction, compared with the FRS, by improving net reclassification by 29%.

**Table 4-1. CAC Scores for the 75th Percentile of Men and Women of Different Race/Ethnic Groups, at Specified Ages**

Age, y	75th Percentile CAC Scores*			
	Black	Chinese	Hispanic	White
<b>Women</b>				
45	0	0	0	0
55	0	2	0	1
65	26	45	19	54
75	138	103	116	237
<b>Men</b>				
45	0	3	0	0
55	15	34	27	68
65	95	121	141	307
75	331	229	358	820

CAC indicates coronary artery calcification.

\*The 75th percentile CAC score is the score at which 75% of people of the same age, sex, and race have a score at or below this level, and 25% of people of the same age, sex, and race have a higher score.

**Chart 4-2.** Prevalence (%) of coronary calcium: US adults 45 to 84 years of age.  $P < 0.0001$  across ethnic groups in both men and women. Data derived from Bild et al.<sup>5</sup>

**Chart 4-3.** Hazard ratios for coronary heart disease (CHD) events associated with coronary calcium scores: US adults 45 to 84 years of age (reference group coronary artery calcification=0). All hazard ratios  $P < 0.0001$ . Major CHD events included myocardial infarction and death due to CHD; any CHD events included major CHD events plus definite angina or definite or probable angina followed by revascularization. Data derived from Detrano et al.<sup>6</sup>

**Chart 4-4.** Hazard ratios for coronary heart disease events associated with coronary calcium scores: US adults (reference group coronary artery calcification (CAC)=0 and Framingham Risk Score <10%). Coronary heart disease events included nonfatal myocardial infarction and death due to coronary heart disease. Data derived from Greenland et al.<sup>7</sup>

**Chart 4-5.** Mean values of carotid intima-media thickness (IMT) for different carotid artery segments in younger adults by race and sex (Bogalusa Heart Study). Data derived from Urbina et al.<sup>11</sup>

**Chart 4-6.** Mean values of carotid intima-media thickness (IMT) for different carotid artery segments in older adults, by race. Data derived from Manolio et al.<sup>15</sup>

## 5. Coronary Heart Disease, Acute Coronary Syndrome, and Angina Pectoris

### Coronary Heart Disease

ICD-9 410 to 414, 429.2; ICD-10 I20 to I25; see Glossary (Chapter 24) for details and definitions. See Tables 5-1 and 5-2. See Charts 5-1 through 5-8.

#### Abbreviations Used in Chapter 5

ACC	American College of Cardiology
ACS	acute coronary syndrome
AHA	American Heart Association
AMI	acute myocardial infarction
AP	angina pectoris
ARIC	Atherosclerosis Risk in Communities study
ATP III	Adult Treatment Panel III
BMI	body mass index
BP	blood pressure
BRFSS	Behavioral Risk Factor Surveillance System
CABG	coronary artery bypass graft
CAD	coronary artery disease
CDC	Centers for Disease Control and Prevention
CHD	coronary heart disease
CHS	Cardiovascular Health Study
CI	confidence interval
CVD	cardiovascular disease
DM	diabetes mellitus
ECG	electrocardiogram
EMS	emergency medical services
FHS	Framingham Heart Study
GRACE	Global Registry of Acute Coronary Events
HD	heart disease
HF	heart failure
ICD	International Classification of Diseases
INTERHEART	Interheart Study
MEPS	Medical Expenditure Panel Survey
MI	myocardial infarction
NAMCS	National Ambulatory Medical Care Survey
NCHS	National Center for Health Statistics
NHAMCS	National Hospital Ambulatory Medical Care Survey
NHANES	National Health and Nutrition Examination Survey
NHDS	National Hospital Discharge Survey
NHIS	National Health Interview Study
NHLBI	National Heart, Lung, and Blood Institute
NRMI	National Registry of Myocardial Infarction
NSTE ACS	non-ST-segment-elevation acute coronary syndromes
NSTEMI	non-ST-segment-elevation myocardial infarction
OR	odds ratio
PA	physical activity
PCI	percutaneous coronary intervention
STEMI	ST-segment-elevation myocardial infarction
UA	unstable angina

#### Prevalence

- On the basis of data from NHANES 2005 to 2008 (NCHS; unpublished NHLBI tabulation (Table 5-1; Chart 5-1), an estimated 16 300 000 Americans  $\geq 20$  years of age have CHD:
  - Total CHD prevalence is 7.0% in US adults  $\geq 20$  years of age. CHD prevalence is 8.3% for men and 6.1% for women.
  - Among non-Hispanic whites, CHD prevalence is 8.5% for men and 5.8% for women.
  - Among non-Hispanic blacks, CHD prevalence is 7.9% for men and 7.6% for women.
  - Among Mexican Americans, CHD prevalence is 6.3% for men and 5.6% for women.
  - Among Hispanic or Latino individuals  $\geq 18$  years of age, CHD prevalence is 5.8% (2009 NHIS, NCHS).<sup>1</sup>
  - Among American Indians/Alaska Natives  $\geq 18$  years of age, it is estimated that 4.1% have CHD (estimate considered unreliable), and among Asians  $\geq 18$  years of age, it is 3.9% (2009 NHIS, NCHS).<sup>1</sup>
- According to data from NHANES 2005 to 2008 (NCHS; unpublished NHLBI tabulation), the overall prevalence for MI is 3.1% in US adults  $\geq 20$  years of age. MI prevalence is 4.3% for men and 2.2% for women.
  - Among non-Hispanic whites, MI prevalence is 4.3% for men and 2.1% for women.
  - Among non-Hispanic blacks, MI prevalence is 4.3% for men and 2.2% for women.
  - Among Mexican Americans, MI prevalence is 3.0% for men and 1.1% for women.
- Data from 2009 from the BRFSS survey of the CDC found that 4.0% of respondents had been told that they had had an MI. The highest prevalence was in West Virginia (6.5%) and Kentucky (5.9%). The lowest prevalence was in the District of Columbia (1.9%). In the same survey, 3.8% of respondents were told that they had angina or CHD. The highest prevalence was in West Virginia (7.1%), and the lowest was in the District of Columbia (2.0%).<sup>2</sup>

#### Incidence

- On the basis of unpublished data from the ARIC and CHS studies of the NHLBI:
  - This year,  $\approx 785$  000 Americans will have a new coronary attack, and  $\approx 470$  000 will have a recurrent attack. It is estimated that an additional 195 000 silent MIs occur each year. That assumes that  $\approx 21\%$  of the 935 000 first and recurrent MIs are silent.<sup>3,4</sup>
  - The estimated annual incidence of MI is 610 000 new attacks and 325 000 recurrent attacks.
  - Average age at first MI is 64.5 years for men and 70.3 years for women.
- On the basis of the NHLBI-sponsored FHS:
  - CHD makes up more than half of all cardiovascular events in men and women  $< 75$  years of age.<sup>3</sup>

- The lifetime risk of developing CHD after 40 years of age is 49% for men and 32% for women.<sup>5</sup>
- The incidence of CHD in women lags behind men by 10 years for total CHD and by 20 years for more serious clinical events such as MI and sudden death.<sup>3</sup>
- In the NHLBI-sponsored ARIC study, in participants 45 to 64 years of age, the average age-adjusted CHD incidence rates per 1000 person-years were as follows: white men, 12.5; black men, 10.6; white women, 4.0; and black women, 5.1. Incidence rates excluding revascularization procedures were as follows: white men, 7.9; black men, 9.2; white women, 2.9; and black women, 4.9.<sup>6</sup>
- Incidence rates for MI in the NHLBI-sponsored ARIC study are displayed in Charts 5–3 and 5–4, stratified by age, race, and sex. The annual age-adjusted rates per 1000 population of first MI (1987–2001) in ARIC Surveillance (NHLBI) were 4.2 in black men, 3.9 in white men, 2.8 in black women, and 1.7 in white women.<sup>7</sup>
- Analysis of more than 40 years of physician-validated acute myocardial infarction (AMI) data in the FHS study of the NHLBI found that AMI rates diagnosed by ECG criteria declined  $\approx 50\%$  with a concomitant 2-fold increase in rates of AMI diagnosed by blood markers. These findings may explain the paradoxical stability of AMI rates in the United States despite concomitant improvements in CHD risk factors.<sup>8</sup>
- Among American Indians 65 to 74 years of age, the annual rates per 1000 population of new and recurrent MIs were 7.6 for men and 4.9 for women.<sup>9</sup> Analysis of data from NHANES III (1988–1994) and NHANES 1999 to 2002 (NCHS) showed that in adults 20 to 74 years of age, the overall distribution of 10-year risk of developing CHD changed little during this time. Among the 3 racial/ethnic groups, blacks had the highest proportion of participants in the high-risk group.<sup>10</sup>
- Based on data from the NHDS, since the mid-1990s, the rate of hospitalization for MI and in-hospital case fatality rates have decreased.<sup>11</sup>
- From 2002 to 2007, the rates of hospitalization for MI decreased among Medicare beneficiaries. However, the degree of reduction was more significant in whites than African Americans.<sup>12</sup>
- Approximately every 34 seconds, an American will have an MI.
- The percentage of CHD deaths that occurred out of the hospital in 2007 was 70%. According to NCHS mortality data, 286 000 CHD deaths occur out of the hospital or in hospital EDs annually (2007, ICD-10 codes I20 to I25) (NHLBI tabulation of NCHS mortality data).
- A study of 1275 health maintenance organization enrollees 50 to 79 years of age who had cardiac arrest showed that the incidence of out-of-hospital cardiac arrest was 6.0/1000 subject-years in subjects with any clinically recognized HD compared with 0.8/1000 subject-years in subjects without HD. In subgroups with HD, incidence was 13.6/1000 subject-years in subjects with prior MI and 21.9/1000 subject-years in subjects with HF.<sup>15</sup>

### Temporal Trends in CHD Mortality

### Mortality

- CHD caused  $\approx 1$  of every 6 deaths in the United States in 2007. CHD mortality was 406 351.<sup>13</sup>
- CHD any-mention mortality was 571 402. MI mortality was 132 968. MI any-mention mortality was 172 538 (NHLBI tabulation; NCHS public-use data files). The 2007 CHD death rate was 126.0.<sup>13</sup> CHD is the largest major killer of American males and females.<sup>13</sup>
- Approximately every 25 seconds, an American will experience a coronary event, and approximately every minute, someone will die of one.
- Approximately 34% of the people who experience a coronary attack in a given year will die of it, and  $\approx 15\%$  who experience a heart attack (MI) will die of it (AHA computation).
- On the basis of data from the FHS of the NHLBI<sup>3</sup>:
  - Fifty percent of men and 64% of women who die suddenly of CHD have no previous symptoms of this disease. Between 70% and 89% of sudden cardiac deaths occur in men, and the annual incidence is 3 to 4 times higher in men than in women; however, this disparity decreases with advancing age.
  - People who have had an MI have a sudden death rate 4 to 6 times that of the general population.
- According to data from the National Registry of Myocardial Infarction<sup>18</sup>:
  - From 1990 to 1999, in-hospital AMI mortality declined from 11.2% to 9.4%.

- Mortality rate increases for every 30 minutes that elapse before a patient with ST-segment elevation is recognized and treated.
- CHD death rates have fallen from 1968 to the present. Analysis of NHANES (NCHS) data compared CHD death rates between 1980 and 2000 to determine how much of the decline in deaths due to CHD over that period could be explained by the use of medical and surgical treatments versus changes in CVD risk factors (resulting from lifestyle/behavior). After 1980 and 2000 data were compared, it was estimated that  $\approx 47\%$  of the decrease in CHD deaths was attributable to treatments, including the following<sup>19</sup>:
  - Secondary preventive therapies after MI or revascularization (11%).
  - Initial treatments for AMI or unstable angina (UA; 10%).
  - Treatments for HF (9%).
  - Revascularization for chronic angina (5%).
  - Other therapies (12%), including antihypertensive and lipid-lowering primary prevention therapies.
- It was also estimated that a similar amount of the reduction in CHD deaths,  $\approx 44\%$ , was attributable to changes in risk factors, including the following<sup>19</sup>:
  - Lower total cholesterol (24%).
  - Lower SBP (20%).
  - Lower smoking prevalence (12%).
  - Decreased physical inactivity (5%).
  - Nevertheless, these favorable improvements in risk factors were offset in part by increases in BMI and in diabetes mellitus prevalence, which accounted for an increased number of deaths (8% and 10%, respectively).
- Between 1980 and 2002, death rates due to CHD among men and women  $\geq 65$  years of age fell by 52% in men and 49% in women. Among men, the death rate declined on average by 2.9% per year in the 1980s, 2.6% per year during the 1990s, and 4.4% per year from 2000 to 2002. Among women, death rates fell by 2.6%, 2.4%, and 4.4%, respectively. However, when stratified by age, among men 35 to 54 years of age, the average annual rate of death fell by 6.2%, 2.3%, and 0.5%, respectively. Among women 35 to 54 years of age, the average annual rate of death fell by 5.4% and 1.2% and then increased by 1.5%, respectively. This increase was not statistically significant; however, in even younger women (35 to 44 years of age), the rate of death has been increasing by an average of 1.3% annually between 1997 and 2002, which is statistically significant.<sup>20</sup>
- An analysis of 28 studies published from 1977 to 2007 found that revascularization by coronary bypass surgery or percutaneous intervention in conjunction with medical therapy in patients with nonacute CAD is associated with significantly improved survival compared with medical therapy alone.<sup>21</sup>
- A recent analysis of Centers for Medicare & Medicaid Services data suggest that between 1995 and 2006, the 30-day mortality rate from MI decreased, as has hospital variation in mortality from MI.<sup>22</sup>
- Data from the Nationwide Inpatient Sample database suggest that mortality from MI have decreased since 1988.<sup>23</sup>

### **Risk Factors**

- Risk factors for CHD act synergistically to increase CHD risk, as shown in the example in Chart 5-6.
- A study of men and women in 3 prospective cohort studies found that antecedent major CHD risk factor exposures were common among those who developed CHD. Approximately 90% of patients with CHD have prior exposure to at least 1 of these major risk factors, which include high total blood cholesterol levels or current medication with cholesterol-lowering drugs, hypertension or current medication with BP-lowering drugs, current cigarette use, and clinical report of diabetes mellitus.<sup>24</sup>
- According to a case-control study of 52 countries (INTERHEART), optimization of 9 easily measured and potentially modifiable risk factors could result in a 90% reduction in the risk of an initial AMI. The effect of these risk factors is consistent in men and women across different geographic regions and by ethnic group, which makes the study applicable worldwide. These 9 risk factors include cigarette smoking, abnormal blood lipid levels, hypertension, diabetes mellitus, abdominal obesity, a lack of PA, low daily fruit and vegetable consumption, alcohol overconsumption, and psychosocial index.<sup>25</sup>
- A study of >3000 members of the FHS (NHLBI) Offspring Cohort without CHD showed that among men with 10-year predicted risk for CHD of 20%, both failure to reach target heart rate and ST-segment depression more than doubled the risk of an event, and each metabolic equivalent increment in exercise capacity reduced risk by 13%.<sup>26</sup>
- A study of non-Hispanic white people 35 to 74 years of age in the FHS (NHLBI) and the NHANES III (NCHS) studies showed that 26% of men and 41% of women had at least 1 borderline risk factor in NHANES III. It is estimated that >90% of CHD events will occur in individuals with at least 1 elevated risk factor and that  $\approx 8\%$  will occur in people with only borderline levels of multiple risk factors. Absolute 10-year CHD risk exceeded 10% both in men >45 years of age who had 1 elevated risk factor and  $\geq 4$  borderline risk factors and in those who had  $\geq 2$  elevated risk factors. In women, absolute CHD risk was >10% only in those >55 years of age who had  $\geq 3$  elevated risk factors.<sup>27</sup>
- A recent analysis examined the number and combination of risk factors necessary to exceed Adult Treatment Panel III (ATP III) treatment thresholds. In this analysis, relatively high risk factor levels were required to exceed ATP III treatment thresholds in men <45 years of age and women <65 years of age, which suggests that alternative means of risk prediction that focus on a longer time horizon than the 10 years captured by the traditional Framingham CHD risk score may be necessary to estimate risk in these individuals.<sup>28</sup>
- Analysis of data from the CHS study (NHLBI) among participants  $\geq 65$  years of age at entry into the study

showed that subclinical CVD is prevalent among older individuals, is independently associated with risk of CHD (even over a 10-year follow-up period), and substantially increases the risk of CHD among participants with hypertension or DM.<sup>29</sup>

- On the basis of data from the CDC/BRFSS, it was found that patients with CHD are less likely to comply with PA recommendations than are subjects without CHD. Only 32% of CHD patients met moderate PA recommendations, 22% met vigorous PA recommendations, and 40% met total PA recommendations. In contrast, the percentage of subjects without CHD who met PA recommendations was significantly higher, and this percentage almost achieved the Healthy People 2010 objectives for PA.<sup>30</sup>
- Analysis of data from the PREMIER trial (Prospective Registry Evaluating Myocardial Infarction: Events and Recovery), sponsored by the NHLBI, found that in people with prehypertension or stage 1 hypertension, 2 multicomponent behavioral interventions significantly reduced estimated 10-year CHD risk by 12% and 14%, respectively, compared with advice only.<sup>31</sup>

#### *Awareness of Warning Signs and Risk Factors for HD*

- Data from the Women Veterans Cohort showed that 42% of women  $\geq 35$  years of age were concerned about HD. Only 8% to 20% were aware that CAD is the major cause of death for women.<sup>32</sup>
- Among people in 14 states and Washington, DC, participating in the 2005 BRFSS, only 27% were aware of 5 heart attack warning signs and symptoms (1, pain in jaw, neck, or back; 2, weak, lightheaded, or faint; 3, chest pain or discomfort; 4, pain or discomfort in arms or shoulder; and 5, shortness of breath) and indicated that they would first call 911 if they thought someone was having a heart attack or stroke. Awareness of all 5 heart attack warning signs and symptoms and the need to call 911 was higher among non-Hispanic whites (30.2%), women (30.8%), and those with a college education or more (33.4%) than among non-Hispanic blacks and Hispanics (16.2% and 14.3%, respectively), men (22.5%), and those with less than a high school education (15.7%), respectively. By state, awareness was highest in West Virginia (35.5%) and lowest in Washington, DC (16.0%).<sup>33</sup>
- A 2004 national study of physician awareness and adherence to CVD prevention guidelines showed that fewer than 1 in 5 physicians knew that more women than men die each year of CVD.<sup>34</sup>
- A recent community surveillance study in 4 US communities reported that in 2000, the overall proportion of people with delays of  $\geq 4$  hours from onset of AMI symptoms to hospital arrival was 49.5%. The study also reported that from 1987 to 2000, there was no statistically significant change in the proportion of patients whose delays were  $\geq 4$  hours, which indicates that there has been little improvement in the speed at which patients with MI symptoms arrive at the hospital after symptom onset. Although the proportion of patients with MI who arrived at the hospital by EMS increased over this period, from 37% in 1987% to

55% in 2000, the total time between onset and hospital arrival did not change appreciably.<sup>35</sup>

- According to 2003 data from the BRFSS (CDC), 36.5% of all women surveyed had multiple risk factors for HD and stroke. The age-standardized prevalence of multiple risk factors was lowest in whites and Asians. After adjustment for age, income, education, and health coverage, the odds for multiple risk factors were greater in black and Native American women and lower for Hispanic women than for white women. Prevalence estimates and odds of multiple risk factors increased with age; decreased with education, income, and employment; and were lower in those with no health coverage. Smoking was more common in younger women, whereas older women were more likely to have medical conditions and to be physically inactive.<sup>36</sup>
- Individuals with documented CHD have 5 to 7 times the risk of having a heart attack or dying as the general population. Survival rates improve after a heart attack if treatment begins within 1 hour; however, most patients are admitted to the hospital 2.5 to 3 hours after symptoms begin. More than 3500 patients surveyed with a history of CHD were asked to identify possible symptoms of heart attack. Despite their history of CHD, 44% had low knowledge levels. In this group, who were all at high risk of future AMI, 43% assessed their risk as less than or the same as others their age. More men than women perceived themselves as being at low risk, at 47% versus 36%, respectively.<sup>37</sup>
- Data from Worcester, MA, indicate that the average time from symptom onset to hospital arrival has not improved and that delays in hospital arrival are associated with less receipt of guidelines-based care. Mean and median prehospital delay times from symptom onset to arrival at the hospital were 4.1 and 2.0 hours in 1986 and 4.6 and 2.0 hours in 2005. Compared with those arriving within 2 hours of symptom onset, those with prolonged prehospital delay were less likely to receive thrombolytic therapy and percutaneous coronary intervention (PCI) within 90 minutes of hospital arrival.<sup>38</sup>
- In an analysis from ARIC, low neighborhood household income (odds ratio [OR] 1.46, 95% confidence interval [CI], 1.09 to 1.96) and being a Medicaid recipient (OR 1.87, 95% CI, 1.10 to 3.19) were associated with increased odds of having prolonged prehospital delays from symptom onset to hospital arrival for AMI compared with individuals with higher neighborhood household income and other insurance providers, respectively.<sup>39</sup>

#### *Aftermath*

- Depending on their sex and clinical outcome, people who survive the acute stage of an MI have a chance of illness and death 1.5 to 15 times higher than that of the general population. Among these people, the risk of another MI, sudden death, AP, HF, and stroke—for both men and women—is substantial (FHS, NHLBI).<sup>3</sup>
- A Mayo Clinic study found that cardiac rehabilitation after an MI is underused, particularly in women and the elderly. Women were 55% less likely than men to participate in cardiac rehabilitation, and older study patients were less

- likely to participate than younger participants. Only 32% of men and women  $\geq 70$  years of age participated in cardiac rehabilitation compared with 66% of those 60 to 69 years of age and 81% of those  $< 60$  years of age.<sup>40</sup>
- On the basis of pooled data from the FHS, ARIC, and CHS studies of the NHLBI, within 1 year after a first MI:
    - At  $\geq 45$  years of age, 19% of men and 26% of women will die.
    - At 45 to 64 years of age, 5% of white men, 9% of white women, 14% of black men, and 8% of black women will die.
    - At  $\geq 65$  years of age, 25% of white men, 30% of white women, 25% of black men, and 30% of black women will die.
    - In part because women have MIs at older ages than men, they are more likely to die of MIs within a few weeks.
  - Within 5 years after a first MI:
    - At  $\geq 45$  years of age, 36% of men and 47% of women will die.
    - At 45 to 64 years of age, 11% of white men, 18% of white women, 22% of black men, and 28% of black women will die.
    - At  $\geq 65$  years of age, 46% of white men, 53% of white women, 54% of black men, and 58% of black women will die.
  - Of those who have a first MI, the percentage with a recurrent MI or fatal CHD within 5 years is:
    - At 45 to 64 years of age, 15% of men and 22% of women.
    - At  $\geq 65$  years of age, 22% of men and women.
    - At 45 to 64 years of age, 14% of white men, 18% of white women, 22% of black men, and 28% of black women.
    - At  $\geq 65$  years of age, 21% of white men and women, 33% of black men, and 26% of black women.
  - The percentage of people with a first MI who will have HF in 5 years is:
    - At 45 to 64 years of age, 8% of men and 18% of women.
    - At  $\geq 65$  years of age, 20% of men and 23% of women.
    - At 45 to 64 years of age, 7% of white men, 15% of white women, 13% of black men, and 25% of black women.
    - At  $\geq 65$  years of age, 19% of white men, 23% of white women, 31% of black men, and 24% of black women.
  - The percentage of people with a first MI who will have a stroke within 5 years is:
    - At 45 to 64 years of age, 2% of men and 6% of women.
    - At  $\geq 65$  years of age, 5% of men and 8% of women.
    - At 45 to 64 years of age, 2% of white men, 4% of white women, 3% of black men, and 10% of black women.
    - At  $\geq 65$  years of age, 5% of white men, 8% of white women, 9% of black men, and 10% of black women.
  - The median survival time (in years) after a first MI is:
    - At 55 to 64 years of age, 17.0 for men and 13.3 for women.
    - At 65 to 74 years of age, 9.3 for men and 8.8 for women.
    - At  $\geq 75$  years of age, 3.2 for men and 3.2 for women.
  - Among survivors of an MI, in 2005, 34.7% of BRFSS respondents participated in outpatient cardiac rehabilitation. The prevalence of cardiac rehabilitation was higher among older age groups ( $\geq 50$  years of age), among men versus women, among Hispanics, among those who were married, among those with higher education, and among those with higher levels of household income.<sup>41</sup>
  - A recent analysis of Medicare claims data revealed that only 13.9% of Medicare beneficiaries enroll in cardiac rehabilitation after an AMI, and only 31% enroll after CABG. Older people, women, nonwhites, and individuals with comorbidities were less likely to enroll in cardiac rehabilitation programs.<sup>42</sup>

#### *Hospital Discharges and Ambulatory Care Visits*

(See Table 5-1 and Chart 5-7.)

- From 1997 to 2007, the number of inpatient discharges from short-stay hospitals with CHD as the first-listed diagnosis decreased from 2 090 000 to 1 572 000 (NHDS, NCHS, NHLBI).
- In 2008, there were 16 251 000 ambulatory care visits with CHD as the first-listed diagnosis (NCHS, NAMCS, NHAMCS). The majority of these visits (62.2%) were for coronary atherosclerosis.<sup>43</sup>
- Age-adjusted hospitalization rate for MI was 215 per 100 000 people in 1979 to 1981, increased to 342 in 1985 to 1987, stabilized for the next decade and then declined after 1996 to 242 in 2003 to 2005. Rates for men were almost twice that of women. Trends were similar for men and women. Hospitalization rates increased with age and were the highest among  $\geq 85$  years.<sup>11</sup>
- Most hospitalized patients  $> 65$  years of age are women. For MI, 28.4% of hospital stays for people 45 to 64 years of age were for women, but 63.7% of stays for those  $\geq 85$  years of age were for women. Similarly, for coronary atherosclerosis, 32.7% of stays among people 45 to 64 years of age were for women; this figure increased to 60.7% of stays among those  $\geq 85$  years of age. For nonspecific chest pain, women were more numerous than men among patients  $< 65$  years of age. Approximately 54.4% of hospital stays among people 45 to 64 years of age were for women. Women constituted 73.9% of nonspecific chest pain stays among patients  $\geq 85$  years of age, higher than for any other condition examined. For AMI, one third more women than men died in the hospital: 9.3% of women died in the hospital compared with 6.2% of men.<sup>44</sup>

#### *Operations and Procedures*

- In 2007, an estimated 1 178 000 inpatient PCI procedures, 408 000 inpatient bypass procedures, 1 061 000 inpatient

diagnostic cardiac catheterizations, 111 000 inpatient implantable defibrillators, and 358 000 pacemaker procedures were performed for inpatients in the United States. (NHLBI, NCHS, unpublished tabulation).

### Cost

- The estimated direct and indirect cost of heart disease in 2007 is \$177.5 billion. (MEPS, NHLBI tabulation).
- In 2006, \$11.7 billion was paid to Medicare beneficiaries for in-hospital costs when CHD was the principal diagnosis (\$14 009 per discharge for AMI, \$12 977 per discharge for coronary atherosclerosis, and \$10 630 per discharge for other ischemic HD).<sup>37,45</sup>

### Acute Coronary Syndrome

ICD-9 codes 410, 411.

The term acute coronary syndrome (ACS) is increasingly used to describe patients who present with either AMI or unstable angina (UA). (UA is chest pain or discomfort that is accelerating in frequency or severity and may occur while at rest but does not result in myocardial necrosis.) The discomfort may be more severe and prolonged than typical AP or may be the first time a person has AP. UA, non-ST-segment-elevation myocardial infarction (NSTEMI), and STEMI share common pathophysiological origins related to coronary plaque progression, instability, or rupture with or without luminal thrombosis and vasospasm.

- A conservative estimate for the number of discharges with ACS from hospitals in 2007 is 671 000. Of these, an estimated 384 000 are males and 287 000 are females. This estimate is derived by adding the first-listed inpatient hospital discharges for MI (577 000) to those for UA (94 000; NHDS, NHLBI).
- When secondary discharge diagnoses in 2007 were included, the corresponding number of inpatient hospital discharges was 1 172 000 unique hospitalizations for ACS; 667 000 were males, and 505 000 were females. Of the total, 731 000 were for MI alone, 431 000 were for UA alone, and 10 000 hospitalizations received both diagnoses (NHDS, NHLBI).

Decisions about medical and interventional treatments are based on specific findings noted when a patient presents with ACS. Such patients are classified clinically into 1 of 3 categories according to the presence or absence of ST-segment elevation on the presenting ECG and abnormal (“positive”) elevations of myocardial biomarkers such as troponins as follows:

- STEMI
- NSTEMI
- UA

The percentage of ACS or MI cases with ST-segment elevation varies in different registries/databases and depends heavily on the age of patients included and the type of surveillance used. According to the National Registry of Myocardial Infarction 4 (NRMI-4), ≈29% of patients with MI are patients with STEMI.<sup>46</sup> The AHA Get With The

Guidelines project found that 32% of the patients with MI in the CAD module are patients with STEMI (personal communication from AHA Get With The Guidelines staff, October 1, 2007). The Global Registry of Acute Coronary Events (GRACE) study, which includes US patient populations, found that 38% of ACS patients have STEMI, whereas the second Euro Heart Survey on ACS (EHS-ACS-II) reported that ≈47% of patients with ACS have STEMI.<sup>47</sup>

In addition, the percentage of ACS or MI cases with ST-segment elevation appears to be declining. In an analysis of 46 086 hospitalizations for ACS in the Kaiser Permanente Northern California study, the percentage of MI cases with ST-segment elevation decreased from 48.5% to 24% between 1999 and 2008.<sup>17</sup>

- Analysis of data from the GRACE multinational observational cohort study of patients with ACS found evidence of a change in practice for both pharmacological and interventional treatments in patients with either STEMI or NSTEMI ACS. These changes have been accompanied by significant decreases in the rates of in-hospital death, cardiogenic shock, and new MI among patients with non-ST-segment-elevation acute coronary syndromes (NSTEMI ACS). The use of evidence-based therapies and PCI interventions increased in the STEMI population. This increase was matched with a statistically significant decrease in the rates of death, cardiogenic shock, and HF or pulmonary edema.<sup>48</sup>
- A study of patients with NSTEMI ACS treated at 350 US hospitals found that up to 25% of opportunities to provide American College of Cardiology (ACC)/AHA guideline-recommended care were missed in current practice. The composite guideline adherence rate was significantly associated with in-hospital mortality.<sup>48</sup>
- A study of hospital process performance in 350 centers of nearly 65 000 patients enrolled in the CRUSADE (Can Rapid Risk Stratification of Unstable Angina Patients Suppress Adverse Outcomes With Early Implementation of the ACC/AHA Guidelines) National Quality Improvement Initiative found that ACC/AHA guideline-recommended treatments were adhered to in 74% of eligible instances.<sup>49</sup>
- After adjustment for clinical differences and the severity of CAD by angiogram, 30-day mortality after ACS is similar in men and women.<sup>50</sup>

### Angina Pectoris

ICD-9 413; ICD-10 I20. See Table 5-2 and Chart 5-5.

#### Prevalence

- A study of 4 national cross-sectional health examination studies found that among Americans 40 to 74 years of age, the age-adjusted prevalence of AP was higher among women than men. Increases in the prevalence of AP occurred for Mexican American men and women and African American women but were not statistically significant for the latter.<sup>51</sup>

**Incidence**

- Only 18% of coronary attacks are preceded by long-standing AP (NHLBI computation of FHS follow-up since 1986).
- The annual rates per 1000 population of new episodes of AP for nonblack men are 28.3 for those 65 to 74 years of age, 36.3 for those 75 to 84 years of age, and 33.0 for those  $\geq 85$  years of age. For nonblack women in the same age groups, the rates are 14.1, 20.0, and 22.9, respectively. For black men, the rates are 22.4, 33.8, and 39.5, and for black women, the rates are 15.3, 23.6, and 35.9, respectively (CHS, NHLBI).<sup>7</sup>
- On the basis of 1987 to 2001 data from the ARIC study of the NHLBI, the annual rates per 1000 population of new episodes of AP for nonblack men are 8.5 for those 45 to 54 years of age, 11.9 for those 55 to 64 years of age, and 13.7 for those 65 to 74 years of age. For nonblack women in the same age groups, the rates are 10.6, 11.2, and 13.1, respectively. For black men, the rates are 11.8, 10.6, and 8.8, and for black women, the rates are 20.8, 19.3, and 10.0, respectively.<sup>7</sup>

**Mortality**

A small number of deaths resulting from CHD are coded as being due to AP. These are included as a portion of total deaths from CHD.

**Cost**

For women with nonobstructive CHD enrolled in the Women's Ischemia Syndrome Evaluation (WISE) study of the NHLBI, the average lifetime cost estimate was  $\approx$ \$770 000 and ranged from \$1.0 to \$1.1 million for women with 1-vessel to 3-vessel CHD.<sup>52</sup>

CHD indicates coronary heart disease; MI, myocardial infarction; NH, non-Hispanic.

CHD includes people who responded "yes" to at least one of the questions in "Has a doctor or other health professional ever told you had coronary heart disease, angina or angina pectoris, heart attack, or myocardial infarction?" Those who answered "no" but were diagnosed with Rose angina are also included. Ellipses indicate data not available. Sources: Prevalence: National Health and Nutrition Examination Survey 2005–2008 (National Center for Health Statistics) and National Heart, Lung, and Blood Institute. Percentages for racial/ethnic groups are age-adjusted for Americans  $\geq$ 20 years of age. Age-specific percentages are extrapolated to the 2008 US population estimates. These data are based on self-reports. Incidence: Atherosclerosis Risk in Communities study (1987–2004), National Heart, Lung, and Blood Institute. Mortality: National Center for Health Statistics (these data represent underlying cause of death only). Hospital discharges: National Hospital Discharge Survey, National Center for Health Statistics (data include those inpatients discharged alive, dead, or status unknown).

\*Mortality data are for whites and blacks and include Hispanics.

†These percentages represent the portion of total CHD mortality that is for males versus females.

‡Estimates include Hispanics and non-Hispanics. Estimates for whites include other nonblack races.

§National Health Interview Study, National Center for Health Statistics 2009; data are weighted percentages for Americans  $\geq$ 18 years of age.<sup>1</sup>

||Figure not considered reliable.

**Table 5-2. Angina Pectoris**

Population Group	Prevalence, 2008 Age ≥20 y	Incidence of Stable AP, Age ≥45 y	Hospital Discharges, 2007,* All Ages
Both sexes	9 000 000 (3.9%)	500 000	47 000
Males	4 000 000 (3.8%)	320 000	28 000

NH black males	3.3%	...	...
NH black females	5.6%	...	...
Mexican American males	3.6%	...	...
Mexican American females	3.7%	...	...

AP indicates angina pectoris; NH, non-Hispanic. AP is chest pain or discomfort that results from insufficient blood flow to the heart muscle. Stable AP is predictable chest pain on exertion or under mental or emotional stress. The incidence estimate is for AP without myocardial infarction. Ellipses indicate data not available.

Sources: Prevalence: National Health and Nutrition Examination Survey 2005–2008 (National Center for Health Statistics) and National Heart, Lung, and Blood Institute; percentages for racial/ethnic groups are age adjusted for Americans ≥20 years of age. Angina pectoris includes persons who either answered “yes” to the question of ever having angina or angina pectoris or were diagnosed with Rose angina. Estimates from National Health and Nutrition Examination Survey 2005–2008 (National Center for Health Statistics) were applied to 2008 population estimates (≥20 years of age). Incidence: AP uncomplicated by a myocardial infarction or with no myocardial infarction (Framingham Heart Study 1980 to 2001–2003 of the original cohort and 1980 to 1998–2001 of the Offspring Cohort, National Heart, Lung, and Blood Institute). Hospital discharges: National Hospital Discharge Survey, National Center for Health Statistics; data include those inpatients discharged alive, dead, or status unknown.

\*There were 102 000 days of care for discharges with AP from short-stay hospitals in 2007.

Diabetes Mellitus	No	No	Yes	Yes
Cigarettes	No	No	No	Yes

**Chart 5-6.** Estimated 10-year coronary heart disease risk in adults 55 years of age according to levels of various risk factors (Framingham Heart Study). HDL-C indicates high density lipoprotein-cholesterol. Data derived from Wilson et al.<sup>53</sup>

**Chart 5-7.** Hospital discharges for coronary heart disease by sex (United States: 1970–2007). Hospital discharges include people discharged alive, dead, and “status unknown.” Source: National Hospital Discharge Survey/National Center for Health Statistics and National Heart, Lung, and Blood Institute.

**Chart 5-8.** Prevalence of low coronary heart disease risk, overall and by sex (National Health and Nutrition Examination Survey: 1971–2006). Low risk is defined as systolic blood pressure <120 mm Hg and diastolic blood pressure <80 mm Hg; cholesterol <200 mg/dL; body mass index <25 kg/m<sup>2</sup>; currently not smoking cigarettes and no prior myocardial infarction or diabetes mellitus. Source: Personal communication with the National Heart, Lung, and Blood Institute, June 28, 2007.

## 6. Stroke (Cerebrovascular Disease)

ICD-9 430 to 438, ICD-10 I60 to I69. See Tables 6-1 and 6-2 and Charts 6-1 through 6-8.

### Prevalence

- An estimated 7 000 000 Americans  $\geq 20$  years of age have had a stroke (extrapolated to 2008 using NCHS/NHANES 2005 to 2008 data). Overall stroke prevalence during this period is an estimated 3.0% (see Table 6-1).
- According to data from the 2005 BRFSS (CDC), 2.7% of men and 2.5% of women  $\geq 18$  years of age had a history of stroke. Of those with prevalent stroke, 2.3% were non-Hispanic white, 4.0% were non-Hispanic black, 1.6% were Asian/Pacific Islander, 2.6% were Hispanic (of any race), 6.0% were American Indian/Alaska Native, and 4.6% were admixed.<sup>1</sup>
- Data from the 2009 survey of the CDC/BRFSS found that, overall, 2.4% of respondents had been told that they had a stroke. The highest prevalence was in Alabama and Oklahoma (3.9%) and the lowest was in Colorado (1.4%).<sup>2</sup>
- Among blacks  $\geq 18$  years of age, the estimated prevalence of stroke based on the 2009 NHIS was 3.8%; among whites, it was 2.5%; and among Asians, it was 1.3%. Among American Indians/Alaska Natives, the prevalence of stroke is not reported due to its large relative standard error (NHIS, NCHS).<sup>3</sup>
- The prevalence of silent cerebral infarction between 55 and 64 years of age is  $\approx 11\%$ . This prevalence increases to 22% between 65 and 69 years of age, 28% between 70 and 74 years of age, 32% between 75 and 79 years of age, 40% between 80 and 85 years of age, and 43% at  $\geq 85$  years of age. Application of these rates to 1998 US population estimates results in an estimated 13 million people with prevalent silent stroke.<sup>4,5</sup>
- The prevalence of stroke-related symptoms was found to be relatively high in a general population free of a prior diagnosis of stroke or transient ischemic attack. On the basis of data from 18 462 participants enrolled in a national cohort study, 17.8% of the population  $>45$  years of age reported at least 1 symptom. Stroke symptoms were more likely among blacks than whites, among those with lower income and lower educational attainment, and among those with fair to poor perceived health status. Symptoms also were more likely in participants with higher Framingham stroke risk score (Reasons for Geographic and Racial Differences in Stroke study [REGARDS], National Institutes of Neurological Disorders and Stroke [NINDS]).<sup>6</sup>

### Incidence

- Each year,  $\approx 795$  000 people experience a new or recurrent stroke. Approximately 610 000 of these are first attacks, and 185 000 are recurrent attacks (GCNKSS, NINDS, and NHLBI; GCNKSS and NINDS data for 1999 provided July 9, 2008; estimates compiled by NHLBI). Of all strokes, 87% are ischemic, 10% are intracerebral hemorrhage, and 3% are subarachnoid hemorrhage strokes (GCNKSS, NINDS, 1999).<sup>7</sup>

### Abbreviations Used in Chapter 6

AAICH	anticoagulant-associated intracerebral hemorrhage
AF	atrial fibrillation
ADL	activities of daily living
AHA	American Heart Association
ARIC	Atherosclerosis Risk in Communities study
BASIC	Brain Attack Surveillance in Corpus Christi
BI	Barthel Index
BMI	body mass index
BP	blood pressure
BRFSS	Behavioral Risk Factor Surveillance System
CDC	Centers for Disease Control and Prevention
CHD	coronary heart disease
CHS	Cardiovascular Health Study
CI	confidence interval
CMS	Center for Medicare & Medicaid Services
CREST	Carotid Revascularization Endarterectomy versus Stenting Trial
CVD	cardiovascular disease
DM	diabetes mellitus
ED	emergency department
FHS	Framingham Heart Study
GCNKSS	Greater Cincinnati/Northern Kentucky Stroke Study
HD	heart disease
HDL	high-density lipoprotein
HERS	Heart and Estrogen/Progestin Replacement Study
HHP	Honolulu Heart Program
HUNT	Nord-Trøndelag Health Study
ICD	International Classification of Diseases
KPNC	Kaiser Permanente of Northern California
MEPS	Medical Expenditure Panel Survey
MI	myocardial infarction
mm Hg	millimeters of mercury
MRI	magnetic resonance imaging
NAMCS	National Ambulatory Medical Care Survey
NCHS	National Center for Health Statistics
NH	non-Hispanic
NHAMCS	National Hospital Ambulatory Medical Care Survey
NHANES	National Health and Nutrition Examination Survey
NHDS	National Hospital Discharge Survey
NHIS	National Health Interview Survey
NHLBI	National Heart, Lung, and Blood Institute
NIHSS	National Institutes of Health Stroke Scale
NINDS	National Institutes of Neurological Disorders and Stroke
NOMAS	Northern Manhattan Study
OR	odds ratio
REGARDS	Reasons for Geographic and Racial Differences in Stroke study
RR	relative risk
SCI	silent cerebral infarct
STOP	Stroke Prevention Trial in Sickle Cell Anemia
TIA	transient ischemic attack
tPA	tissue-type plasminogen activator
WASID	Warfarin–Aspirin Symptomatic Intracranial Disease Trial
WEST	Women’s Estrogen for Stroke Trial
WHI	Women’s Health Initiative

- On average, every 40 seconds, someone in the United States has a stroke (AHA computation based on latest available data).
- Analysis of data from the FHS study of the NHLBI suggest that stroke incidence is declining over time. In this largely white cohort, data from 1950 to 1977, 1978 to 1989, and 1990 to 2004, showed that the age-adjusted incidence of first stroke per 1000 person-years in each of the 3 periods was 7.6, 6.2, and 5.3 in men and 6.2, 5.8, and 5.1 in women, respectively. Lifetime risk for incident stroke at 65 years of age decreased significantly in the latest data period compared with the first, from 19.5% to 14.5% in men and from 18.0% to 16.1% in women. Age-adjusted stroke severity did not vary across periods; however, 30-day mortality rate decreased significantly in men (from 23% to 14%), but not in women (from 21% to 20%).<sup>8</sup>
- As compared with the 1990s, when incidence rates of stroke were stable, data from 2005 showed that stroke incidence was decreasing for whites but not blacks (GCNKSS 2005). Blacks continue to have a higher stroke incidence than whites, especially among young adults (GCNKSS 1999, 2005).
- Blacks have a risk of first-ever stroke that is almost twice that of whites. The age-adjusted stroke incidence rates in people 45 to 84 years of age are 6.6 per 1000 population in black men, 3.6 in white men, 4.9 in black women, and 2.3 in white women (ARIC, NHLBI).<sup>7</sup> On the basis of 1987 to 2001 data from the ARIC study sponsored by the NHLBI, stroke/transient ischemic attack (TIA) incidence rates (per 1000 person-years) are 2.4 for white men 45 to 54 years of age, 6.1 for white men 55 to 64 years of age, and 12.2 for white men 65 to 74 years of age. For white women in the same age groups, the rates are 2.4, 4.8, and 9.8, respectively. For black men in the same age groups, the rates are 9.7, 13.1, and 16.2, and for black women, the rates are 7.2, 10.0, and 15.0, respectively.<sup>7</sup>
- A study of nearly 18 000 middle-aged, predominantly white male participants in the Physicians' Health Study found that the Southeast and Midwest had higher crude and age-standardized major CVD, total stroke, ischemic stroke, coronary revascularization, and CVD death incidence rates compared with the Northeast.<sup>9</sup>
- Each year, ≈55 000 more women than men have a stroke (GCNKSS, NINDS).
- National statistics from death certificate data have long shown an increase in deaths attributed to stroke for blacks because of a higher stroke incidence compared with whites, although the case-fatality rate is similar between the 2 racial groups. This racial disparity in stroke incidence does not seem to be changing over time. Community socioeconomic status appeared to explain 39% of the excess stroke incidence risk in blacks in this study.<sup>10</sup>
- The BASIC project (NINDS) demonstrated an increased incidence of stroke among Mexican Americans compared with non-Hispanic whites in this community. The crude 3-year cumulative incidence was 168 per 10 000 in Mexican Americans and 136 per 10 000 in non-Hispanic whites. Specifically, Mexican Americans have a higher cumulative incidence for ischemic stroke at younger ages (45 to 59 years of age: RR 2.04; 95% CI, 1.55 to 2.69; 60 to 74 years of age: RR 1.58; 95% CI, 1.31 to 1.91), but not at older ages (≥75 years of age: RR 1.12; 95% CI, 0.94 to 1.32). Mexican Americans also have a higher incidence of intracerebral hemorrhage and subarachnoid hemorrhage than non-Hispanic whites, adjusted for age.<sup>11</sup>
- Among 4507 American Indian participants without a prior stroke in the Strong Heart Study in 1989 to 1992, the age- and sex-adjusted incidence of stroke through 2004 was 6.79 per 100 person-years, with 86% of incident strokes being ischemic.<sup>12</sup>
- The age-adjusted incidence of first ischemic stroke per 100 000 was 88 in whites, 191 in blacks, and 149 in Hispanics, according to data from the Northern Manhattan Study (NOMAS) (NINDS). Among blacks, compared with whites, the relative rate of intracranial atherosclerotic stroke was 5.85; extracranial atherosclerotic stroke, 3.18; lacunar stroke, 3.09; and cardioembolic stroke, 1.58. Among Hispanics (primarily Cuban and Puerto Rican), compared with whites, the relative rate of intracranial atherosclerotic stroke was 5.00; extracranial atherosclerotic stroke, 1.71; lacunar stroke, 2.32; and cardioembolic stroke, 1.42.<sup>13</sup>
- Analysis of black and white patients in the Warfarin–Aspirin Symptomatic Intracranial Disease (WASID) trial found that blacks were significantly more likely to have an ischemic stroke, brain hemorrhage or vascular death, or ischemic stroke alone than whites.<sup>14</sup>
- A review of published studies and data from clinical trials found that hospital admissions for intracerebral hemorrhage have increased by 18% in the past 10 years, probably because of increases in the number of elderly people, many of whom lack adequate blood pressure control, and the increasing use of anticoagulants, thrombolytics, and antiplatelet agents. Mexican Americans, Latin Americans, blacks, Native Americans, Japanese people, and Chinese people have higher incidences than do white Americans.<sup>15</sup>
- In the GCNKSS, the annual incidence of anticoagulant-associated intracerebral hemorrhage (AAICH) per 100 000 people was 0.8 (95% CI, 0.3 to 1.3) in 1988, 1.9 (95% CI, 1.1 to 2.7) in 1993/1994, and 4.4 (95% CI, 3.2 to 5.5) in 1999 ( $P < 0.001$  for trend). Among people aged ≥80, the AAICH rate increased from 2.5 (95% CI, 0 to 7.4) in 1988 to 45.9 (95% CI, 25.6 to 66.2) in 1999 ( $P < 0.001$  for trend). Incidence rates of cardioembolic ischemic stroke were similar in 1993/1994 and 1999 (31.1 versus 30.4,  $P = 0.65$ ). Warfarin distribution in the United States quadrupled on a per-capita basis between 1988 and 1999.<sup>16</sup>

### Transient Ischemic Attack

- The number of TIAs in the United States has been estimated to be ≈200 000 to 500 000 per year, with a population prevalence of 2.3%, which translates into ≈5 million people.<sup>17</sup>
- The prevalence of TIA increases significantly with older age.<sup>18</sup>
- In population-based studies, the age- and sex-adjusted incidence rates for TIA range from 68.2 to 83.0 per 100 000. Men, blacks and Mexican Americans have higher rates of TIA.<sup>11,19</sup>

- Meta-analyses of cohorts of patients with TIA have shown the short-term risk of stroke after TIA to be  $\approx 3\%$  to  $10\%$  at 2 days and  $9\%$  to  $17\%$  at 90 days.<sup>20,21</sup>
- In the North American Symptomatic Carotid Endarterectomy Trial, patients with a first-ever hemispheric TIA had a 90-day stroke risk of  $20\%$ . The risk of stroke after TIA exceeded the risk after hemispheric stroke.<sup>22</sup>
- Individuals who have a TIA have a 10-year stroke risk of roughly  $19\%$  and a combined 10-year stroke, MI, or vascular death risk of  $43\%$  ( $4\%/year$ ).<sup>23</sup>
- Approximately  $15\%$  of all strokes are heralded by a TIA.<sup>18</sup>
- Within 1 year of TIA, about  $12\%$  to  $13\%$  of patients will die.<sup>24,25</sup>
- Approximately half of all patients who experience a TIA fail to report it to their healthcare providers.<sup>26</sup>
- One third of episodes characterized as TIAs according to the classic definition (ie, focal neurological deficits that resolve within 24 hours) would be considered infarctions on the basis of diffusion-weighted MRI findings.<sup>27</sup>
- In a study of people  $\geq 65$  years of age recruited from a random sample of Health Care Financing Administration Medicare Part B eligibility lists in 4 US communities, the 1-month case fatality rate was  $12.6\%$  for all strokes,  $8.1\%$  for ischemic strokes, and  $44.6\%$  for hemorrhagic strokes.<sup>31</sup>
- More women than men die of stroke each year due to the larger number of elderly women. Women accounted for  $60.6\%$  of US stroke deaths in 2007.
- From 1995 to 1998, age-standardized mortality rates for ischemic stroke, subarachnoid hemorrhage, and intracerebral hemorrhage were higher among blacks than whites. Death rates from intracerebral hemorrhage also were higher among Asians/Pacific Islanders than among whites. All minority populations had higher death rates from subarachnoid hemorrhage than did whites. Among adults 25 to 44 years of age, blacks and American Indians/Alaska Natives had higher risk ratios than did whites for all 3 stroke subtypes.<sup>32</sup>
- In 2002, death certificate data showed that the mean age at stroke death was 79.6 years; however, males had a younger mean age at stroke death than females. Blacks, American Indians/Alaska Natives, and Asians/Pacific Islanders had younger mean ages than whites, and the mean age at stroke death was also younger among Hispanics than non-Hispanics.<sup>33</sup>
- Age-adjusted stroke mortality rates began to level off in the 1980s and stabilized in the 1990s for both men and women, according to the Minnesota Heart Study. Women had lower rates of stroke mortality than did men throughout the period. Some of the improvement in stroke mortality may be the result of improved acute stroke care, but most is thought to be the result of improved detection and treatment of hypertension.<sup>34</sup>
- A report released by the CDC in collaboration with the Center for Medicare & Medicaid Services (CMS), the *Atlas of Stroke Hospitalizations Among Medicare Beneficiaries*, found that in Medicare beneficiaries, 30-day mortality rate varied by age:  $9\%$  in patients 65 to 74 years of age,  $13.1\%$  in those 74 to 84 years of age, and  $23\%$  in those  $\geq 85$  years of age.<sup>35</sup>
- There are substantial geographic disparities in stroke mortality with higher rates in the southeastern US known as the “stroke belt.” This area is usually defined to include the eight southern states of North Carolina, South Carolina, Georgia, Tennessee, Mississippi, Alabama, Louisiana, and Arkansas. These geographic differences have existed since at least 1940<sup>36</sup> and despite some minor shifts,<sup>37</sup> they still persist.<sup>38–40</sup> Within the stroke belt, a “buckle” region along the coastal plain of North Carolina, South Carolina, and Georgia has been identified with even a higher stroke mortality rate than the remainder of the stroke belt.<sup>41</sup> The overall average stroke mortality is  $\approx 20\%$  higher in the stroke belt than in the rest of the nation and  $\approx 40\%$  higher in the stroke buckle.

## Mortality

- On average, every 4 minutes, someone dies of a stroke (NCHS, NHLBI).<sup>28</sup>
- Stroke accounted for  $\approx 1$  of every 18 deaths in the United States in 2007.<sup>28</sup>
- When considered separately from other CVDs, stroke ranks No. 3 among all causes of death, behind diseases of the heart and cancer (NCHS mortality data). Preliminary data from the CDC released on December 9, 2010, suggest that, using the 10th version of the *International Classification of Diseases (ICD-10)* and reclassification of some respiratory diseases, cerebrovascular disease may now rank No. 4 among all causes of death, after diseases of the heart, cancer, and chronic lower respiratory diseases.<sup>28a</sup>
- Stroke mortality in 2007 was 135 952; any-mention mortality in 2007 was 227 215 and the death rate was  $42.2$ .<sup>28</sup> See Chart 6-2 for sex/race comparison.
- From 1997 to 2007, the annual stroke death rate decreased  $34.3\%$ , and the actual number of stroke deaths declined  $18.8\%$  (appropriate comparability ratios were applied) (NCHS Health Data Interactive Web site <http://www.cdc.gov/nchs/hdi.htm> accessed on July 15, 2010).
- Conclusions about changes in stroke death rates from 1980 to 2005:
  - There was a greater decline in stroke death rates in men than in women, with a male-to-female ratio decreasing from 1.11 to 1.03 (age-adjusted).
  - There were greater declines in stroke death rates in men than in women among people  $\geq 65$  years of age compared with younger ages.<sup>29</sup>
- Approximately  $54\%$  of stroke deaths in 2007 occurred out of the hospital (unpublished NHLBI tabulation of NCHS 2007 Mortality Data Set).
- Among people 45 to 64 years of age,  $8\%$  to  $12\%$  of ischemic strokes and  $37\%$  to  $38\%$  of hemorrhagic strokes result in death within 30 days, according to the ARIC study of the NHLBI.<sup>30</sup>

## Stroke Risk Factors

(See Table 6-2 for data on modifiable stroke risk factors.)

- TIAs confer a substantial short-term risk of stroke, hospitalization for CVD events, and death. Of 1707 TIA patients evaluated in the ED of Kaiser Permanente Northern Cali-

fornia, a large integrated healthcare delivery system, 180 (10%) experienced a stroke within 90 days. Ninety-one patients (5%) had a stroke within 2 days. Predictors of stroke included age >60 years, DM, focal symptoms of weakness or speech impairment, and TIA that lasted >10 minutes.<sup>42</sup>

- BP is a powerful determinant of risk for both ischemic stroke and intracranial hemorrhage. Subjects with BP <120/80 mm Hg have approximately half the lifetime risk of stroke of subjects with hypertension. The treatment and lowering of blood pressure among hypertensive individuals was associated with a significant reduction in stroke risk.<sup>43</sup>
- In REGARDS (NINDS), black participants were more aware than whites of their hypertension and more likely to be undergoing treatment if aware of their diagnosis, but among those treated for hypertension, they were less likely than whites to have their BP controlled. There was no evidence of a difference between the stroke belt and other regions in awareness of hypertension, but there was a trend for better treatment and BP control in the stroke belt region. The lack of substantial geographic differences in hypertension awareness and the trend toward better treatment and control in the stroke belt suggest that differences in hypertension management may not be a major contributor to the geographic disparity in stroke mortality.<sup>44</sup>
- Impaired glucose tolerance nearly doubled the stroke risk as compared with patients with normal glucose levels and tripled the risks for patients with diabetes mellitus.<sup>45</sup>
- Atrial fibrillation (AF) is a powerful risk factor for stroke, independently increasing risk ≈5-fold throughout all ages. The percentage of strokes attributable to AF increases steeply from 1.5% at 50 to 59 years of age to 23.5% at 80 to 89 years of age.<sup>46,47</sup>
- As AF is often asymptomatic<sup>48,49</sup> and likely frequently clinically undetected,<sup>50</sup> the stroke risk attributed to AF may be substantially underestimated.<sup>51</sup> Therefore, although AF is an important stroke risk factor, both patients and treating physicians may be unaware of its presence. A related point is that no strategy to pursue normal sinus rhythm, including cardioversion, antiarrhythmic drug therapy and/ or ablation, has definitively been shown to reduce the risk of stroke.
- The risk of ischemic stroke associated with current cigarette smoking has been shown to be approximately double that of nonsmokers after adjustment for other risk factors (FHS, CHS, Honolulu Heart Program [HHP], NHLBI).
- Age-specific incidence rates and rate ratios show that diabetes increases ischemic stroke incidence at all ages, but this risk is most prominent before 55 years of age in blacks and before 65 years of age in whites. Ischemic stroke patients with DM are younger, more likely to be black, and more likely to have hypertension, MI, and high cholesterol than nondiabetic patients.<sup>52</sup>
- In a recent ARIC/NHLBI study of a biracial population 45 to 64 years of age, with an average follow-up of 13.4 years, researchers found that blacks had a 3-fold higher multivariate-adjusted risk ratio of lacunar stroke than whites. In this middle-aged population, the top 3 risk factors based on the population-attributable fraction for lacunar stroke were

hypertension (population-attributable fraction, 33.9%), DM (26.3%), and current smoking (22.0%).<sup>53</sup>

- In the Framingham Offspring Study, 2040 individuals free of clinical stroke had an MRI scan to detect silent cerebral infarct (SCI). Prevalent SCI was associated with the Framingham Stroke Risk Profile score (OR 1.27; 95% CI, 1.10 to 1.46), hypertension (OR 1.56; 95% CI, 1.15 to 2.11), elevated plasma homocysteine (OR 2.23; 95% CI, 1.42 to 3.51), AF (OR 2.16; 95% CI, 1.07 to 4.40), carotid stenosis >25% (OR 1.62; 95% CI, 1.13 to 2.34), and increased carotid intimal-medial thickness (OR 1.65; 95% CI, 1.22 to 2.24).<sup>54</sup>
- In the FHS of the NHLBI, in participants <65 years of age, the risk of developing stroke/TIA was 4.2-fold higher in those with symptoms of depression. After adjustment for components of the Framingham Stroke Risk Profile and education, similar results were obtained. In subjects ≥65 years of age, use of antidepressant medications did not alter the risk associated with depressive symptoms. Identification of depressive symptoms at younger ages may have an impact on the primary prevention of stroke.<sup>55</sup>
- Data from the HHP/NHLBI found that in Japanese men 71 to 93 years of age, low concentrations of HDL cholesterol were more likely to be associated with a future risk of thromboembolic stroke than were high concentrations.<sup>56</sup>

### Risk Factor Issues Specific to Women

- Analysis of NHANES 1999 to 2004 data found that women 45 to 54 years of age are more than twice as likely as men to have had a stroke. Women in the 45- to 54-year age group had a >4-fold higher likelihood of having had a stroke than women 35 to 44 years of age.<sup>57</sup>
- Women are older at stroke onset compared with men (75 years compared with 71 years).<sup>58</sup>
- Women have lower age-adjusted stroke incidence than men; however, sex differences in stroke risk are modified by age. Data from Framingham demonstrate that compared with white men, white women 45 to 84 years have lower stroke risk than men, but this association is reversed in older ages such that women greater than 85 years have elevated risk compared with men.<sup>58</sup> Similarly, a population-based study in Sweden found stroke incidence to be 60% lower for women than men at ages 55 to 64 years, but by 75 years of age this association reversed and women had a 50% higher incidence than men.<sup>59</sup> The Oxford Vascular Study also showed lower stroke incidence for women than men aged 55 to 74 years, but higher incidence for women aged 85 years and older.<sup>60</sup>
- Lifetime risk of stroke is greater in women compared with men because of their greater life expectancy and the fact that stroke rates increase substantially with age.<sup>61</sup>
- Overall, randomized clinical trial data indicate that the use of estrogen plus progestin, as well as estrogen alone, increases stroke risk in postmenopausal, generally healthy women and provides no protection for women with established HD.<sup>62,63</sup>
- Among postmenopausal women who were generally healthy, the Women's Health Initiative (WHI), a random-

ized trial of 16 608 women (95% of whom had no preexisting CVD), found that estrogen plus progestin increased ischemic stroke risk by 44%, with no effect on hemorrhagic stroke. The excess risk was apparent in all age groups, in all categories of baseline stroke risk, and in women with and without hypertension or prior history of CVD.<sup>62</sup>

- In the WHI trial, among 10 739 women with hysterectomy, it was found that conjugate equine estrogen alone increased the risk of ischemic stroke by 55% and that there was no significant effect on hemorrhagic stroke. The excess risk of total stroke conferred by estrogen alone was 12 additional strokes per 10 000 person-years.<sup>64</sup>
- In postmenopausal women with known CHD, the Heart and Estrogen/Progestin Replacement Study (HERS), a secondary CHD prevention trial, found that a combination of estrogen plus progestin (conjugated equine estrogen [0.625 mg] and medroxyprogesterone acetate [2.5 mg]) hormone therapy did not reduce stroke risk.<sup>65</sup>
- The Women's Estrogen for Stroke Trial (WEST) found that estrogen alone (1 mg of 17 $\beta$ -estradiol) in women with a mean age of 71 years also had no significant overall effect on recurrent stroke or fatality, but there was an increased rate of fatal stroke and an early increase in overall stroke rate in the first 6 months of therapy.<sup>66</sup>
- Analysis of data from the FHS found that women with menopause at 42 to 54 years of age and at  $\geq 55$  years of age had lower stroke risk compared with those with menopause <42 years of age, even after adjustment for potential confounders. Women with menopause before 42 years of age had twice the stroke risk compared with all other women in different age groups.<sup>67</sup>
- The preponderance of evidence supports an increased risk of ischemic stroke among users of low-estrogen oral contraception.<sup>68–70</sup> An increased relative risk of 1.93 (95% CI, 1.35 to 2.74) was found for low-estrogen preparations in population-based studies that controlled for smoking and hypertension. This translates to an additional 4.1 ischemic strokes per 100 000 nonsmoking, normotensive women using low-estrogen oral contraceptives, or 1 additional ischemic stroke per year per 24 000 such women.<sup>69</sup>
- The risk of ischemic stroke or intracerebral hemorrhage during pregnancy and the first 6 weeks postpartum was 2.4 times greater than for nonpregnant women of similar age and race, according to the Baltimore-Washington Cooperative Young Stroke Study. The risk of ischemic stroke during pregnancy was not increased during pregnancy per se but was increased 8.7-fold during the 6 weeks postpartum. Intracerebral hemorrhage showed a small RR of 2.5 during pregnancy but increased dramatically to an RR of 28.3 in the 6 weeks postpartum. The excess risk of stroke (all types except subarachnoid hemorrhage) attributable to the combined pregnancy/postpregnancy period was 8.1 per 100 000 pregnancies.<sup>71</sup>
- In the US Nationwide Inpatient Sample from 2000 to 2001, the rate of events per 100 000 pregnancies was 9.2 for ischemic stroke, 8.5 for intracerebral hemorrhage, 0.6 for cerebral venous thrombosis, and 15.9 for the ill-defined category of pregnancy-related cerebrovascular events, for a total rate of 34.2 per 100 000, not including subarachnoid

hemorrhage. The risk was increased in blacks and among older women. Death occurred during hospitalization in 4.1% of women with these events and in 22% of survivors after discharge to a facility other than home.<sup>72</sup>

- Preeclampsia is a risk factor for ischemic stroke remote from pregnancy.<sup>73</sup> The subsequent stroke risk of preeclampsia may be mediated by a 3.6 to 6.1-fold higher later risk of hypertension and a 3.1 to 3.7-fold higher later risk of diabetes mellitus, depending on whether the preeclampsia was mild or severe.<sup>74</sup>

### Physical Inactivity as a Risk Factor for Stroke

Higher levels of physical activity are associated with lower stroke risk. This relationship has been consistently demonstrated in prospective and case-control studies conducted in the United States as well as in a variety of other populations.

- Results from the Physicians' Health Study showed a 14% lower RR of stroke associated with vigorous exercise (exercise  $\geq 5$  times per week) among men.<sup>75</sup>
- The Harvard Alumni Study showed that men who were highly physically active had an 18% lower RR of total stroke.<sup>76</sup>
- In the Women's Health Study, a dose-response relationship between level of leisure-time walking time and pace and risk of stroke was demonstrated, with higher levels of activity associated with 20% to 40% reduction in risk.<sup>77</sup>
- In NOMAS, a prospective cohort that included white, black, and Hispanic men and women in an urban setting who were followed for a median of 9 years, baseline physical activity was associated with an overall 35% reduction in risk of ischemic stroke.<sup>78</sup>
- In this analysis, an interaction between sex and activity intensity was seen, with moderate to heavy activity associated with a 60% reduction in risk of ischemic stroke in men, but no association was seen in women.<sup>78</sup>
- The NOMAS study found that only moderate to vigorous intensity exercise was associated with reduced stroke incidence, whereas light exercise (such as walking) showed no benefit.<sup>78</sup>
- In a subanalysis of data from the ARIC study, blacks reporting sports-related activity had a 40% reduced risk of subclinical MRI-detected cerebral infarct after 6 years of follow-up.<sup>79</sup>
- In contrast to studies showing little or no benefit at lower levels of exercise,<sup>78,80–82</sup> several reports indicate a protective effect of relatively light exposure. After a median of 16 years of follow-up in the Nord-Trøndelag Health Study (HUNT),<sup>83</sup> a single weekly episode of vigorous exercise was associated with a 50% reduction in the risk of dying from stroke in men, with no additional benefit seen with more frequent exercise. Recent findings from the Women's Health Study<sup>77</sup> also demonstrated an inverse association between stroke incidence and walking, but no clear relationship with vigorous-intensity activity.
- Timing of physical activity in relation to stroke onset has also been examined in several studies. In a hospital-based

case-control study from Heidelberg, Germany, recent activity (within the prior months) was associated with reduced odds of having a stroke or transient ischemic attack, whereas sports activity during young adulthood that was not continued showed no benefit.<sup>84</sup> In a Danish case-control study, ischemic stroke patients were less physically active in the week preceding the stroke compared with age- and sex-matched controls, with the highest activity scores associated with greatest reduction in odds of stroke.<sup>85</sup>

### Awareness of Stroke Warning Signs and Risk Factors

- Correct knowledge of at least 1 stroke warning sign increased from 48% in 1995 to 68% in 2000, with no significant improvement to 2005 (68%) based on a telephone survey conducted in a biracial population in the greater Cincinnati/Northern Kentucky region. Knowledge of 3 correct warning signs was low, but increased over time; 5.4% in 1995, 12.0% in 2000, and 15.7% in 2005. Knowledge of at least 1 stroke risk factor increased from 59% in 1995 to 71% in 2000, but there was not improvement to 2005 (71%). Only 3.6% of those surveyed were able to independently identify tissue-type plasminogen activator (tPA) as an available drug therapy and only 9% of these were able to identify a window of <3 hours for treatment.<sup>86</sup>
- In the 2005 BRFSS among respondents in 14 states, 38.1% were aware of 5 stroke warning symptoms and would first call 9-1-1 if they thought that someone was having a heart attack or stroke. Awareness of all 5 stroke warning symptoms and calling 9-1-1 was higher among whites versus blacks and Hispanics (41.3%, 29.5%, and 26.8%, respectively), women versus men (41.5% versus 34.5%), and people with higher versus lower educational attainment (47.6% for people with a college degree or more versus 22.5% for those who had not received a high school diploma). Among states, the same measure ranged from 27.9% (Oklahoma) to 49.7% (Minnesota).<sup>87</sup>
- A study was conducted of patients admitted to an ED with possible stroke to determine their knowledge of the signs, symptoms, and risk factors of stroke. Of the 163 patients able to respond, 39% did not know a single sign or symptom. Patients  $\geq 65$  years of age were less likely than those <65 years old to know a sign or symptom of stroke (28% versus 47%), and 43% did not know a single risk factor. Overall, almost 40% of patients did not know the signs, symptoms, and risk factors of stroke.<sup>88</sup>
- Among patients recruited from the Academic Medical Center Consortium, the CHS, and United HealthCare, only 41% were aware of their increased risk for stroke. Approximately 74% recalled being told of their increased stroke risk by a physician, compared with 28% who did not recall this. Younger patients, depressed patients, those in poor current health, and those with a history of TIA were most likely to be aware of their risk.<sup>89</sup>
- An AHA-sponsored random-digit dialing telephone survey was conducted in mid-2003. Only 26% of women >65

years of age reported being well informed about stroke. Correct identification of the warning signs of stroke was low among all age and racial/ethnic groups.<sup>90</sup>

- Among participants in a study by the National Stroke Association, 2.3% reported having been told by a physician that they had had a TIA. Of those with a TIA, only 64% saw a physician within 24 hours of the event, only 8.2% correctly related the definition of TIA, and 8.6% could identify a typical symptom. Men, people of color, and those with lower income and fewer years of education were less likely to be knowledgeable about TIA.<sup>19</sup>
- In 2004, 800 adults  $\geq 45$  years of age were surveyed to assess their perceived risk for stroke and their history of stroke risk factors. Overall, 39% perceived themselves to be at risk. Younger age, current smoking, a history of DM, high BP, high cholesterol, HD, and stroke/TIA were independently associated with perceived risk for stroke. Respondents with AF were no more likely to report being at risk than were respondents without AF. Perceived risk for stroke increased as the number of risk factors increased; however, 46% of those with  $\geq 3$  risk factors did not perceive themselves to be at risk.<sup>91</sup>
- A study of patients who have had a stroke found that only 60.5% were able to accurately identify 1 stroke risk factor and that 55.3% were able to identify 1 stroke symptom. Patients' median delay time from onset of symptoms to admission in the ED was 16 hours, and only 31.6% accessed the ED in <2 hours. Analysis showed that the appearance of nonmotor symptoms as the primary symptom and nonuse of the 9-1-1 system were significant predictors of delay >2 hours. Someone other than the patient made the decision to seek treatment in 66% of the cases.<sup>92</sup>
- Spanish-speaking Hispanics are less likely to know all stroke symptoms than English-speaking Hispanics, non-Hispanic blacks, and non-Hispanic whites. Lack of English proficiency is strongly associated with lack of stroke knowledge among Hispanics.<sup>93</sup>

### Aftermath

Stroke is a leading cause of serious, long-term disability in the United States (Survey of Income and Program Participation, a survey of the US Bureau of the Census).<sup>94</sup>

- Data from the BRFSS (CDC) 2005 survey on stroke survivors in 21 states and the District of Columbia found that 30.7% of stroke survivors received outpatient rehabilitation. The findings indicated that the prevalence of stroke survivors receiving outpatient stroke rehabilitation was lower than would be expected if clinical practice guideline recommendations for all stroke patients had been followed.
- On the basis of pooled data from the FHS, ARIC, and CHS studies of the NHLBI:
  - The proportions of patients dead 1 year after a first stroke were as follows:
    - At  $\geq 45$  years of age: 28% of men and 32% of women
    - At 45 to 64 years of age: 16% of white men, 21% of white women, 19% of black men, and 19% of black women

- At  $\geq 65$  years of age: 31% of white men, 35% of white women, 27% of black men, and 29% of black women
- The proportions of patients dead within 5 years after a first stroke were as follows:
  - At  $\geq 45$  years of age: 52% of men and 56% of women
  - At 45 to 64 years of age: 27% of white men, 31% of white women, 36% of black men, and 42% of black women
  - At  $\geq 65$  years of age: 58% of white men, 61% of white women, 52% of black men, and 53% of black women
- Of those who have a first stroke, the proportions with a recurrent stroke in 5 years were as follows:
  - At 45 to 64 years of age: 10% of men and 20% of women
  - At  $\geq 65$  years of age: 20% of men and 25% of women
  - At 45 to 64 years of age: 13% of white men, 15% of white women, 6% of black men, and 23% of black women
  - At  $\geq 65$  years of age: 21% of white men, 25% of white women, 12% of black men, and 23% of black women
- The median survival times after a first stroke were:
  - At 55 to 64 years of age: 13.1 years for men and 7.8 years for women
  - At 65 to 74 years of age: 6.2 years for men and 7.7 years for women
  - At  $\geq 75$  years of age: 2.1 years for men and 2.3 years for women
- The length of time to recover from a stroke depends on its severity. Between 50% and 70% of stroke survivors regain functional independence, but 15% to 30% are permanently disabled, and 20% require institutional care at 3 months after onset.<sup>96</sup>
- In the NHLBI's FHS, among ischemic stroke survivors who were  $\geq 65$  years of age, these disabilities were observed at 6 months after stroke<sup>97</sup>:
  - 50% had some hemiparesis
  - 30% were unable to walk without some assistance
  - 26% were dependent in activities of daily living (ADLs)
  - 19% had aphasia
  - 35% had depressive symptoms
  - 26% were institutionalized in a nursing home
- Black stroke survivors had greater activity limitations than did white stroke survivors, according to data from the NHIS (2000 to 2001, NCHS) as analyzed by the CDC.<sup>98</sup>
- After stroke, women have greater disability than men. A Michigan-based stroke registry found that 33% of women had moderate to severe disability (modified Rankin score  $\geq 4$ ) at discharge, compared with 27% of men. In a study of

108 stroke survivors from FHS, 34% of women were disabled at 6 months (Barthel Index [BI]  $< 60$ ), compared with 16% of men. In the Kansas City Stroke Study, women had a 30% lower probability of achieving independence (BI  $\geq 95$ ) by 6 months compared with men. In the Michigan registry, women had a 63% lower probability of achieving ADL independence (BI  $\geq 95$ ) 3 months after discharge.<sup>97,99–101</sup>

### Hospital Discharges/Ambulatory Care Visits

- From 1997 to 2007, the number of inpatient discharges from short-stay hospitals with stroke as the first listed diagnosis declined from 1 018 000 to 829 000 (NHDS, NCHS). Most of the decrease was observed in men and women  $\geq 65$  years of age. (NHLBI tabulation, NHDS, NCHS)
- In 2005, there was a hospitalization rate of 77.3 stays per 10 000 people  $> 45$  years of age for cerebrovascular disease. There has been a decline in the hospitalization rate for different types of cerebrovascular disease between 1997 and 2005, with the exception of hemorrhagic stroke. Between 1997 and 2005, the hospitalization rate for ischemic stroke decreased by 34%, from 54.4 to 35.9 stays per 10 000 people. The hospitalization rate for transient cerebral ischemia also decreased  $\approx 23\%$  during this period. Similarly, the hospitalization rate for occlusion or stenosis of precerebral arteries steadily decreased by 30% between 1997 and 2005, from 18.4 to 12.8 stays per 10 000 people. In contrast, the hospitalization rate for hemorrhagic stroke remained relatively stable during this period.<sup>102</sup>
- Data from 2007 from the Hospital Discharge Survey of the NCHS showed that the average length of stay for discharges with stroke as the first-listed diagnosis was 5.3 days.
- In 2003, men and women accounted for roughly the same number of hospital stays for stroke in the 18- to 44-year age group. After 65 years of age, women were the majority. Among people 65 to 84 years of age, 54.5% of stroke patients were women, whereas among the oldest age group, women constituted 69.7% of all stroke patients.<sup>103</sup>
- A first-ever county-level *Atlas of Stroke Hospitalizations Among Medicare Beneficiaries* was released in 2008 by the CDC in collaboration with the CMS. It found that the stroke hospitalization rate for blacks was 27% higher than for the US population in general, 30% higher than for whites, and 36% higher than for Hispanics. In contrast to whites and Hispanics, the highest percentage of strokes in blacks (42.3%) occurred in the youngest Medicare age group (65 to 74 years of age).<sup>35</sup>
- In 2008, the number of ambulatory care visits with stroke as the first-listed diagnosis was 3 726 000 (NAMCS, NHAMCS/NCHS).<sup>104</sup>

### Stroke in Children

- On the basis of pathogenic differences, pediatric strokes are typically classified as either perinatal, occurring at  $\leq 28$  days of life and including in utero strokes, or (later) childhood.

- Recent estimates of the overall annual incidence of stroke in US children are 6.4 per 100 000 children (0 to 15 years) in 1999 in GCNKSS<sup>105</sup> and 4.6 per 100 000 children (0 to 19 years) from 1997 to 2003 Kaiser Permanente of Northern California (KPNC), a large integrated healthcare delivery system.<sup>106</sup> Approximately half of incident childhood strokes are hemorrhagic.<sup>107</sup>
- The prevalence of perinatal strokes is 29 per 100 000 live births, or one per 3500 live births in the 1997 to 2003 KPNC population.<sup>106</sup>
- A history of infertility, preeclampsia, prolonged rupture of membranes, and chorioamnionitis were found to be independent risk factors for perinatal arterial ischemic stroke in KPNC. The RR of perinatal stroke increased  $\approx$ 25-fold, with an absolute risk of 1 per 200 deliveries, when  $\geq$ 3 of antenatally determined risk factors were present.<sup>108</sup>
- Although children with sickle cell disease and congenital HD are at high risk for ischemic stroke, the most common cause in a previously healthy child is a cerebral arteriopathy, found in approximately two thirds of cases.<sup>109</sup>
- Thrombophilias (genetic and acquired) are risk factors for childhood stroke, with summary ORs ranging from 1.6 to 8.8 in a recent meta-analysis.<sup>110</sup>
- From 1979 to 1998 in the United States, childhood mortality resulting from stroke declined by 58% overall, with reductions in all major subtypes.<sup>111</sup>
- The incidence of stroke in children has been stable over the past 10 years, whereas the 30-day case fatality rates were 18% in 1988 to 1989, 9% in 1993 to 1994, and 9% in 1999 in the GCNKSS population. The previously reported nationwide decrease in overall stroke mortality in children might be due to decreasing case fatality after stroke and not decreasing stroke incidence.<sup>105</sup>
- Compared with girls, boys have a 1.28-fold higher risk of stroke.<sup>112</sup> Compared with white children, black children have a 2-fold risk of both incident stroke and death from stroke.<sup>111,112</sup> The increased risk among blacks is not fully explained by the presence of sickle cell disease, nor is the excess risk among boys fully explained by trauma.<sup>112</sup>
- At a mean follow-up time of 2.1 years, 37% of 123 childhood ischemic stroke survivors had full recovery, 20% had mild deficits, 26% had moderate deficits, and 16% had severe deficits.<sup>113</sup> Concomitant involvement of the basal ganglia, cerebral cortex, and posterior limb of the internal capsule predicts a persistent hemiparesis.<sup>114</sup>
- After adjusting for routine healthcare costs, the average 5-year cost of a neonatal stroke was \$51 719 and of a childhood stroke was \$135 161. Costs in children with stroke continued to exceed that in age-matched control children even in the fifth year by an average of \$2016.<sup>115</sup>
- Despite current treatment, 1 of 10 children with ischemic or hemorrhagic stroke will have a recurrence within 5 years.<sup>116,117</sup> The 5-year recurrence risk is as high as 60% among children with cerebral arteriopathy. The recurrence risk after perinatal stroke, however, is negligible.<sup>118</sup>
- Sickle cell disease is the most important cause of ischemic stroke among black children. The Stroke Prevention Trial in Sickle Cell Anemia (STOP), reported in 1998, demonstrated the efficacy (reduction of stroke from 10% per year

to <1%) of blood transfusions for primary stroke prevention in high-risk children with sickle cell disease identified by transcranial Doppler. First-admission rates for stroke in California among children with sickle cell disease showed a dramatic decline subsequent to the publication of the STOP study.<sup>119</sup>

- A second randomized clinical trial, STOP II, demonstrated that stopping transfusions after 30 months of treatment was associated with a high risk of stroke.<sup>120</sup>

### Barriers to Stroke Care

- Based on NHIS data, the inability to afford medications among stroke survivors increased significantly from 8.1% to 12.7% between 1997 to 2004, totaling 76 000 US stroke survivors in 2004. Compared with stroke survivors able to afford medications, those unable more frequently reported lack of transportation, no health insurance, no usual place of care, income <\$20 000 and out-of-pocket medical expenses  $\geq$ \$2000.<sup>121</sup>
- In 2002,  $\approx$ 21% of US counties did not have a hospital, 31% lacked a hospital with an ED, and 77% did not have a hospital with neurological services.<sup>122</sup>
- Of patients with ischemic stroke in the California Acute Stroke Pilot Registry, 23.5% arrived at the ED within 3 hours of symptom onset, and 4.3% received thrombolysis. If all patients had called 9-1-1 immediately, the expected overall rate of thrombolytic treatment within 3 hours would have increased to 28.6%. If all patients with known onset had arrived within 1 hour and had been optimally treated, 57% could have received thrombolytic treatment.<sup>123</sup>
- Data from the Paul Coverdell National Acute Stroke Registry were analyzed from the 142 hospitals that participated in the 4 registry states. More patients were transported by ambulance than by other means (43.6%). Time of stroke symptom onset was recorded for 44.8% of the patients. Among these patients, 48% arrived at the ED within 2 hours of symptom onset. Significantly fewer blacks (42.4%) arrived within 2 hours of symptom onset than did whites (49.5%), and significantly fewer nonambulance patients (36.2%) arrived within 2 hours of symptom onset than did patients transported by ambulance (58.6%). The median arrival time for all patients with known time of onset was 2.0 hours. Sixty-five percent of patients who arrived at the ED within 2 hours of onset received imaging within 1 hour of ED arrival. Significantly fewer women (62%) received imaging within 1 hour of ED arrival than men.<sup>124</sup>
- A comprehensive statewide survey of hospital-based stroke prevention and treatment capabilities conducted in all emergent stroke care hospitals in North Carolina in 1998, 2003, and 2008 found that the proportion of hospitals offering certain stroke-related diagnostic tests increased over the 10-year period, with significant increases in CT angiography and diffusion-weighted MRI, but not catheter angiography. Sixteen hospitals received Joint Commission certification as Primary Stroke Centers, servicing 41% of the state's population based on county of residence. In 2008, 96% of hospitals provided CT imaging, 59% pro-

vided diffusion-weighted MRI, 57% had a neurologist on staff, 69% had a tPA protocol, and 27% had a stroke team. Despite increases in the accessibility of specific diagnostic tests and improvements in hospitals' organizational features, there were no major differences in hospitals' offerings of stroke education programs in their communities.<sup>125</sup>

- NHIS data from 1998 to 2002 found that younger stroke survivors (45 to 64 years) self-reported worse access to physician care and medication affordability than older stroke survivors. Compared with older patients, younger stroke survivors were more likely to be male (47% versus 52%), black (10% versus 19%), and to lack health insurance (0.4% versus 11%). Lack of health insurance was associated with reduced access to care.<sup>126</sup>
- Data from 142 hospitals participating in the Paul Coverdell National Acute Stroke Registry found that fewer than 48% of stroke patients arrived at the ED within 2 hours of symptom onset in 2005 to 2006. Blacks were less likely to arrive within the 2-hour window compared with whites (42.4% versus 49.5%). Among those arriving within 2 hours, 65.2% received imaging within 1 hour of ED arrival; significantly fewer women received imaging within 1 hour as compared with men (62.9% versus 67.6%), but no differences were observed by racial group.<sup>127</sup>
- Results from the Brain Attack Surveillance in Corpus Christi (BASIC) project found that women were less likely to arrive at the ED within 3 hours of stroke symptom onset than men (OR 0.7; 95% CI, 0.5 to 0.9). Mexican Americans were 40% less likely to arrive by EMS than non-Hispanic whites, even after adjustment for age, National Institutes of Health Stroke Scale (NIHSS), education, history of stroke, and insurance status. Language fluency was not associated with time to hospital arrival or use of EMS. The receipt of tPA was low (1.5%), but did not differ by sex or race.<sup>128</sup>
- A national study of Academic Medical Centers found no change in the proportion of patients with stroke arriving at hospitals within 2 hours of symptom onset between 2001 and 2004 (37% versus 38%); however, the rate of IV tPA use increased over this time period (14% to 38%), suggesting system-level improvements in the organization of in-hospital care. In risk-adjusted analyses, black patients were 45% less likely to arrive within 2 hours compared with white patients.<sup>129</sup>
- Receipt of time-sensitive interventions such as fibrinolytic therapy for acute stroke is contingent on access to an appropriately staffed emergency department. In 2003, 71% of the US population had access to an ED within 30 minutes, and 98% within 60 minutes. Access to teaching hospitals was more limited (16% within 30 minutes, 44% within 60 minutes). Although the majority of the US population had access to an ED within 60 minutes, rural states had lower access to all types of EDs, indicating geographic heterogeneity in rapid access to emergency care; 30-minute access ranged from 48% in Vermont to 86% in the District of Columbia.<sup>130</sup>
- A study of 55 094 US veterans with ischemic stroke from 1990 to 1997 found substantial geographic variation in inpatient and outpatient healthcare utilization and outcomes. Patients in the Northeast and West were 30% more

likely than those in the Midwest and South to have a neurology and/or general medicine clinic visit within 60 days of discharge and were also more likely to have both neurology and general medicine follow-up within 1 year. Mortality was lower in regions where more patients had early outpatient care after stroke.<sup>131</sup>

- Patients with a discharge diagnosis of ischemic stroke were identified in 7 California hospitals participating in the California Acute Stroke Pilot Registry. Six points of care were tracked: thrombolysis, receipt of antithrombotic medications within 48 hours, prophylaxis for deep vein thrombosis, smoking cessation counseling, and prescription of lipid-lowering and antithrombotic medications at discharge. Overall, rates of optimal treatment improved for patients treated in year 2 versus year 1, with 63% receiving a perfect score in year 2 versus 44% in year 1. Rates improved significantly in 4 of the 6 hospitals and for 4 of the 6 interventions. A seventh hospital that participated in the registry but did not implement standardized orders showed no improvement in optimal treatment.<sup>132</sup>

### Operations and Procedures

Among stroke or TIA patients with high-grade carotid stenosis, carotid endarterectomy has been the recommended treatment for the prevention of stroke, whereas carotid stenting has been proposed as a therapeutic option for patients at high risk for surgical revascularization.

- In 2005, a total of 66 698 eligible Medicare beneficiaries underwent carotid endarterectomy and 7357 underwent carotid stenting.
- There is substantial geographic variation in the age-adjusted rates of carotid endarterectomy, with a nearly nine-fold difference between the highest rate and the lowest rate.
- The rate of carotid endarterectomy decreased slightly from 2003 (3.2 per 1000 person-years) to 2006 (2.7 per 1000 person-years).
- From 2001 to 2006, there was a significant increase in the use of carotid imaging among Medicare beneficiaries, along with a concurrent decrease in the use of carotid revascularization procedures.
- In 2007, an estimated 91 000 inpatient endarterectomy procedures were performed in the United States. Carotid endarterectomy is the most frequently performed surgical procedure to prevent stroke. (NHDS, NCHS, NHLBI tabulation).
- Although rates of carotid endarterectomy in the Medicare population slightly decreased between 1998 and 2004, the use of carotid artery stenting dramatically increased.<sup>133</sup> (see Chart 6-8)
- The randomized Carotid Revascularization Endarterectomy versus Stenting Trial (CREST) compared carotid endarterectomy and stenting for symptomatic and asymptomatic carotid stenosis. There was no overall difference in the primary end point of stroke, myocardial infarction, or death. However, carotid endarterectomy showed superiority with increasing age, with the crossover point at approximately age 70, and was associated with fewer

strokes, which had a greater impact on quality of life than MI.<sup>134</sup>

## Cost

The direct and indirect cost of stroke in 2007 was \$40.9 billion. (MEPS, NHLBI tabulation)

- The estimated direct medical cost of stroke for 2007 is \$25.2 billion. This includes hospital outpatient or office-based provider visits, hospital inpatient stays, emergency room visits, prescribed medicines, and home health.<sup>134</sup>
- The mean expenses per person for stroke care in the United States in 2007 was estimated at \$7657.<sup>135</sup>
- The mean lifetime cost of ischemic stroke in the United States is estimated at \$140 048. This includes inpatient care, rehabilitation, and follow-up care necessary for lasting deficits. (All numbers were converted to 1999 dollars by use of the medical component of the Consumer Price Index.)<sup>136</sup>
- The estimated cost of acute pediatric stroke in the United States is \$42 million in 2003. The mean cost of short-term hospital care was \$20 927 per discharge.<sup>137</sup>
- In a study of stroke costs within 30 days of an acute event between 1987 to 1989 in the Rochester Stroke Study, the average cost was \$13 019 for mild ischemic strokes and \$20 346 for severe ischemic strokes (4 or 5 on the Rankin Disability Scale).<sup>138</sup>
- Inpatient hospital costs for an acute stroke event account for 70% of first-year poststroke costs.<sup>106</sup>
- The largest components of short-term-care costs were room charges (50%), medical management (21%), and diagnostic costs (19%).<sup>139</sup>
- Death within 7 days, subarachnoid hemorrhage, and stroke while hospitalized for another condition are associated with higher costs in the first year. Lower costs are associated with mild cerebral infarctions or residence in a nursing home before the stroke.<sup>138</sup>
- Demographic variables (age, sex, and insurance status) are not associated with stroke cost. Severe strokes (NIHSS score >20) cost twice as much as mild strokes, despite similar diagnostic testing. Comorbidities such as ischemic HD and AF predict higher costs.<sup>139,140</sup>
- The total cost of stroke from 2005 to 2050, in 2005 dollars, is projected to be \$1.52 trillion for non-Hispanic whites, \$313 billion for Hispanics, and \$379 billion for blacks. The per capita cost of stroke estimates is highest in blacks (\$25 782), followed by Hispanics (\$17 201) and non-Hispanic whites (\$15 597). Loss of earnings is expected to be the highest cost contributor in each race/ethnic group.<sup>141</sup>

**Table 6-1. Stroke**

Population Group	Prevalence, 2008	New and Recurrent Attacks	Mortality, 2007	Hospital Discharges, 2007	Cost, 2007
	Age $\geq 20$ y	All Ages	All Ages*	All Ages	
Both sexes	7 000 000 (3.0%)	795 000	135 952	829 000	\$40.9 billion
Males	2 800 000 (2.7%)	370 000 (46.5%)†	54 111 (39.8%)†	371 000	
Females	4 200 000 (3.3%)	425 000 (53.5%)†	81 841 (60.2%)†	458 000	
NH white males	2.4%	325 000‡	44 714		
NH white females	3.3%	365 000‡	69 981		
NH black males	4.5%	45 000‡	7549		
NH black females	4.4%	60 000‡	9536		
Mexican-American males	2.0%				
Mexican-American females	2.7%				
Hispanic or Latino, age $\geq 18$ y	2.0%§				
Asian or Pacific Islander, age $\geq 18$ y	1.3%§	3586			
American Indian/ Alaska Native, age $\geq 18$ y	...	586			

NH indicates non-Hispanic.

Ellipses ( . . . ) indicate data not available.

\*Mortality data are for whites and blacks and include Hispanics.

†These percentages represent the portion of total stroke incidence or mortality that applies to males vs females.

‡Estimates include Hispanics and non-Hispanics. Estimates for whites include other nonblack races.

§NHIS (2009), NCHS; data are weighted percentages for Americans  $\geq 18$  years of age.<sup>3</sup>

Sources: Prevalence: National Health and Nutrition Examination Survey 2005 to 2008, National Center for Health Statistics and National Heart, Lung, and Blood Institute. Percentages for racial/ethnic groups are age-adjusted for Americans  $\geq 20$  years of age. Age-specific percentages are extrapolated to the 2008 US population. Incidence: Greater Cincinnati/Northern Kentucky Stroke Study/National Institutes of Neurological Disorders and Stroke data for 1999 provided on August 1, 2007. US estimates compiled by National Heart, Lung, and Blood Institute. See also Kissela et al.<sup>142</sup> Data include children. Mortality: National Center for Health Statistics. These data represent underlying cause of death only. Mortality data for white and black males and females include Hispanics. Hospital discharges: National Hospital Discharge Survey, National Center for Health Statistics. Data include those inpatients discharged alive, dead, or status unknown. Cost: National Heart, Lung, and Blood Institute. Data include estimated direct and indirect costs for 2007.

**Table 6-2. Modifiable Stroke Risk Factors**

Factor	Prevalence, %	Population-Attributable Risk, %*	RR
<b>CVD</b>			
<b>CHD<sup>143</sup></b>			
Men	8.4	5.8†	1.73 (1.68–1.78) <sup>161</sup>
Women	5.6	3.9†	1.55 (1.17–2.07) <sup>162</sup>
<b>Heart failure<sup>143</sup></b>			
Men	2.6	1.4†	
Women	2.1	1.1†	
Peripheral arterial disease	4.9	3.0†	
<b>Hypertension<sup>144</sup></b>			
Age 50 y	20	40	4.0
Age 60 y	30	35	3.0
Age 70 y	40	30	2.0
Age 80 y	55	20	1.4
Age 90 y	60	0	1.0
Cigarette smoking	25	12–18	1.8
Diabetes mellitus	7.3	5–27	1.8–6
Asymptomatic carotid stenosis	2–8 <sup>148–154</sup>	2–7‡	2.0 <sup>162</sup>
<b>Atrial fibrillation (nonvalvular)<sup>145,146</sup></b>			
Age 50–59 y	0.5	1.5	4.0
Age 60–69 y	1.8	2.8	2.6
Age 70–79 y	4.8	9.9	3.3
Age 80–89 y	8.8	23.5	4.5
Sickle cell disease	0.25 (of blacks) <sup>155</sup>		200–400 <sup>163§</sup>
<b>Dyslipidemia</b>			
High total cholesterol	25 <sup>156</sup>	15	2.0 for men and for women <55 y of age
Low HDL cholesterol	25 <sup>156</sup>	10	1.5–2.5 for men
<b>Dietary factors</b>			
Na intake 2300 mg	75–90	Unknown	Unknown
K intake 4700 mg	90–99 <sup>157</sup>	Unknown	Unknown
Obesity	17.9 <sup>158</sup>	12–20†	1.75–2.37 <sup>164,165</sup>
Physical inactivity <sup>147</sup>	25	30	2.7‡
Postmenopausal hormone therapy	20 <sup>159</sup> (women 50–74 y of age) <sup>160</sup>	7	1.4 <sup>63</sup>

RR indicates relative risk; CVD, cardiovascular disease; CHD, coronary heart disease; HDL, high-density lipoprotein.

Data derived from Hart et al<sup>166,167</sup> and van Walraven et al.<sup>168</sup> Stroke includes both ischemic and hemorrhagic stroke. Cardiovascular disease includes coronary heart disease, heart failure, and peripheral arterial disease.

\*Population-attributable risk is the proportion of ischemic stroke in the population that can be attributed to a particular risk factor (see text for formula).

†Calculated on the basis of point estimates of referenced data provided in the table. For peripheral arterial disease, calculation was based on average relative risk for men and women.

‡Calculated based on referenced data provided in the table or text.

§Relative to stroke risk in children without sickle cell disease.

## 7. High Blood Pressure

ICD-9 401 to 404, ICD-10 I10 to I15. See Tables 7-1 and 7-2 and Charts 7-1 through 7-5.

### Prevalence

- HBP is defined as:
  - SBP  $\geq$ 140 mm Hg or DBP  $\geq$ 90 mm Hg or taking antihypertensive medicine, or
  - Having been told at least twice by a physician or other health professional that one has HBP.
- One in 3 US adults has HBP.<sup>1</sup>
- Data from NHANES 1999 to 2006 found that  $\approx$ 8% of US adults have undiagnosed hypertension.<sup>2</sup>
- An estimated 76 400 000 adults  $\geq$ 20 years of age have HBP, extrapolated to 2008 with NHANES 2005 to 2008 data (Table 7-1).
- NHANES data show that a higher percentage of men than women have hypertension until 45 years of age. From 45 to 54 and from 55 to 64 years of age, the percentages of men and women with hypertension are similar. After that, a higher percentage of women have hypertension than men.<sup>3</sup>

### Abbreviations Used in Chapter 7

ARIC	Atherosclerosis Risk in Communities Study
BP	blood pressure
BRFSS	Behavioral Risk Factor Surveillance System
CDC	Centers for Disease Control and Prevention
CHD	coronary heart disease
CHF	congestive heart failure
CHS	Cardiovascular Health Study
CVD	cardiovascular disease
DBP	diastolic blood pressure
DM	diabetes mellitus
FHS	Framingham Heart Study
HBP	high blood pressure
HD	heart disease
HHANES	Hispanic Health and Nutrition Examination Survey
ICD	<i>International Classification of Diseases</i>
LDL	low-density lipoprotein
MEPS	Medical Expenditure Panel Survey
MESA	Multi-Ethnic Study of Atherosclerosis
mm Hg	millimeters of mercury
NCHS	National Center for Health Statistics
NHANES	National Health and Nutrition Examination Survey
NHDS	National Hospital Discharge Survey
NHES	National Health Examination Survey
NHIS	National Health Interview Survey
NHLBI	National Heart, Lung, and Blood Institute
NINDS	National Institute of Neurological Disorders and Stroke
SBP	systolic blood pressure
SEARCH	Search for Diabetes in Youth Study

- HBP is 2 to 3 times more common in women taking oral contraceptives, especially among obese and older women, than in women not taking them.<sup>4</sup>
- Data from NHANES 2005 to 2006 found that 29% of US adults  $\geq$ 18 years of age were hypertensive. The prevalence of hypertension was nearly equal between men and women; 7% of adults had HBP but had never been told that they had hypertension. Among hypertensive adults, 78% were aware of their condition, 68% were using antihypertensive medication, and 64% of those treated had their hypertension controlled.<sup>5</sup>
- Data from the 2009 BRFSS/CDC indicate that the percentage of adults  $\geq$ 18 years of age who had been told that they had HBP ranged from 21.6% in Minnesota to 37.6% in West Virginia. The median percentage was 28.7%.<sup>6</sup>

### Older Adults

- In 2007 to 2008, diagnosed chronic conditions that were more prevalent among older women than men included hypertension (58% for women, 53% for men). Ever-diagnosed conditions that were more prevalent among older men than older women included HD (38% for men, 27% for women) and DM (20% for men, 18% for women) based on data from NHIS/NCHS.<sup>7</sup>
- The age-adjusted prevalence of hypertension (both diagnosed and undiagnosed) in 2003 to 2006 was 75% for older women and 65% for older men on the basis of data from NHANES/NCHS.<sup>8</sup>

### Children and Adolescents

- Analysis of NHES, Hispanic Health and Nutrition Examination Survey (HHANES), and NHANES/NCHS surveys of the NCHS (1963–2002) found that the BP, pre-HBP, and HBP trends in children and adolescents 8 to 17 years of age moved downward from 1963 to 1988 and upward thereafter. Pre-HBP and HBP increased 2.3% and 1%, respectively, between 1988 and 1999. Increased obesity (more so abdominal obesity than general obesity) partially explained the HBP and pre-HBP rise from 1988 to 1999. BP and HBP reversed their downward trends 10 years after the increase in the prevalence of obesity. In addition, an ethnic and sex gap appeared in 1988 for pre-HBP and in 1999 for HBP: Non-Hispanic blacks and Mexican Americans had a greater prevalence of HBP and pre-HBP than non-Hispanic whites, and the prevalence was greater in boys than in girls. In that study, HBP in children and adolescents was defined as SBP or DBP that was, on repeated measurement,  $\geq$ 95th percentile.<sup>9</sup>
- A study in Ohio of >14 000 children and adolescents 3 to 18 years of age who were observed at least 3 times between 1999 and 2006 found that 3.6% had hypertension. Of these, 26% had been diagnosed and 74% were undiagnosed. In addition, 3% of those with hypertension had stage 2 hypertension, and 41% of those with stage 2 hypertension were undiagnosed. Criteria for prehypertension were met by 485 children. Of these, 11% were diagnosed. In this study, HBP in children and adolescents was defined as SBP or DBP that was, on repeated measurement,  $\geq$ 95th percentile.<sup>10</sup>

- A study from 1988 to 1994 through 1999 to 2000 of children and adolescents 8 to 17 years of age showed that among non-Hispanic blacks, mean SBP levels increased by 1.6 mm Hg among girls and by 2.9 mm Hg among boys compared with non-Hispanic whites. Among Mexican Americans, girls' SBP increased 1.0 mm Hg and boys' SBP increased 2.7 mm Hg compared with non-Hispanic whites.<sup>11</sup>
- Analysis of data from the Search for Diabetes in Youth Study (SEARCH), which included children 3 to 17 years of age with type 1 and type 2 DM, found the prevalence of elevated BP among those with type 1 DM to be 5.9% and the prevalence of elevated BP among those with type 2 DM to be 23.7%.<sup>12</sup>

### Race/Ethnicity and HBP

- The prevalence of hypertension in blacks in the United States is among the highest in the world, and it is increasing. From 1988 to 1994 through 1999 to 2002, the prevalence of HBP in adults increased from 35.8% to 41.4% among blacks, and it was particularly high among black women at 44.0%. Prevalence among whites also increased, from 24.3% to 28.1%.<sup>13</sup>
- Compared with whites, blacks develop HBP earlier in life, and their average BPs are much higher. As a result, compared with whites, blacks have a 1.3-times greater rate of nonfatal stroke, a 1.8-times greater rate of fatal stroke, a 1.5-times greater rate of death due caused by HD, and a 4.2-times greater rate of end-stage kidney disease (Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure 5 and 6).
- Within the black community, rates of hypertension vary substantially.<sup>13,14</sup>
  - Those with the highest rates are more likely to be middle-aged or older, less educated, overweight or obese, and physically inactive and are more likely to have DM.
  - Those with the lowest rates are more likely to be younger but also overweight or obese.
  - Those with uncontrolled HBP who are not taking antihypertensive medication tend to be male, to be younger, and to have infrequent contact with a physician.
- Analysis from the REGARDS study of the NINDS suggests that efforts to raise awareness of prevalent hypertension among blacks apparently have been successful (31% greater odds in blacks relative to whites), and efforts to communicate the importance of receiving treatment for hypertension have been successful (69% greater odds among blacks relative to whites); however, substantial racial disparities remain with regard to the control of BP (SBP <140 mm Hg, DBP <90 mm Hg), with the odds of control being 27% lower in blacks than whites. In contrast, geographic disparities in hypertension awareness, treatment, and control were minimal.<sup>15</sup>
- Data from the 2009 NHIS showed that black adults  $\geq 18$  years of age were more likely (32.2%) to have been told on  $\geq 2$  occasions that they had hypertension than American

- Indian/Alaska Native adults (21.8%), white adults (23.0%), and Asian adults (19.4%).<sup>16</sup>
- The CDC analyzed death certificate data from 1995 to 2002 (any-mention mortality; ICD-9 codes 401 to 404 and ICD-10 codes I10 to I13). The results indicated that Puerto Rican Americans had a consistently higher hypertension-related death rate than all other Hispanic subpopulations and non-Hispanic whites. The age-standardized hypertension-related mortality rate was 127.2 per 100 000 population for all Hispanics, similar to that of non-Hispanic whites (135.9). The age-standardized rate for Hispanic females (118.3) was substantially lower than that observed for Hispanic males (135.9). Hypertension-related mortality rates for males were higher than rates for females for all Hispanic subpopulations. Puerto Rican Americans had the highest hypertension-related death rate among all Hispanic subpopulations (154.0); Cuban Americans had the lowest (82.5).<sup>17</sup>
- Some studies suggest that Hispanic Americans have rates of HBP similar to or lower than those of non-Hispanic white Americans. Findings from a new analysis of combined data from the NHIS of 2000 to 2002 point to a health disparity between black and white adults of Hispanic descent. Black Hispanics were at slightly greater risk than white Hispanics, although non-Hispanic black adults had by far the highest rate of HBP. The racial disparity among Hispanics also was evident in the fact that higher-income, better-educated black Hispanics still had a higher rate of HBP than lower-income, less-educated white Hispanics.<sup>18</sup> Data from the NHLBI's ARIC study found that hypertension was a particularly powerful risk factor for CHD in black people, especially black women.<sup>19</sup>
- Data from MESA found that being born outside the United States, speaking a language other than English at home, and living fewer years in the United States were each associated with a decreased prevalence of hypertension.<sup>20</sup>
- Filipino (27%) and Japanese (25%) adults were more likely than Chinese (17%) or Korean (17%) adults to have ever been told that they had hypertension.<sup>21</sup>

### Mortality

HBP mortality in 2007 was 57 732. Any-mention mortality in 2007 was 336 353 (NHLBI tabulation of NCHS mortality data). The 2007 death rate was 17.8.<sup>22</sup>

- From 1997 to 2007, the death rate caused by HBP increased 9.0%, and the actual number of deaths rose 35.6% (NCHS and NHLBI; appropriate comparability ratios were applied).
- The 2007 overall death rate resulting from HBP was 17.8. Death rates were 15.7 for white males, 49.2 for black males, 14.3 for white females, and 37.0 for black females. When any-mention mortality for 2007 was used, the overall death rate was 108.5. Death rates were 108.6 for white males, 228.8 for black males, 90.7 for white females, and 174.8 for black females (NHLBI tabulation of NCHS mortality data).

### Risk Factors

- Numerous risk factors and markers for development of hypertension, including age, ethnicity, family history of

hypertension and genetic factors, lower education and socioeconomic status, greater weight, lower physical activity, tobacco use, psychosocial stressors, sleep apnea, and dietary factors (including dietary fats, higher sodium intake, lower potassium intake, and excessive alcohol intake), have been identified.

- A study of related individuals in the NHLBI's FHS estimated that when measured at a single examination, BP levels are  $\approx 40\%$  heritable; when measured across multiple examinations, long-term BP trends are  $\approx 55\%$  heritable.<sup>23</sup>
- Recent data from the Nurses' Health Study suggest that a large proportion of incident hypertension in women can be prevented by controlling dietary and lifestyle risk factors.<sup>24</sup>

### Aftermath

- Approximately 69% of people who have a first heart attack, 77% of those who have a first stroke, and 74% of those who have CHF have BP  $>140/90$  mm Hg (NHLBI unpublished estimates from ARIC, CHS, and FHS Cohort and Offspring studies).
- Data from FHS/NHLBI indicate that recent (within the past 10 years) and remote antecedent BP levels may be an important determinant of risk over and above the current BP level.<sup>25</sup>
- Data from the FHS/NHLBI indicate that hypertension is associated with shorter overall life expectancy, shorter life expectancy free of CVD, and more years lived with CVD.<sup>26</sup>
  - Total life expectancy was 5.1 years longer for normotensive men and 4.9 years longer for normotensive women than for hypertensives of the same sex at 50 years of age.
  - Compared with hypertensive men at 50 years of age, men with untreated BP  $<140/90$  mm Hg survived on average 7.2 years longer without CVD and spent 2.1 fewer years of life with CVD. Similar results were observed for women.

### Hospital Discharges/Ambulatory Care Visits

- From 1997 to 2007, the number of inpatient discharges from short-stay hospitals with HBP as the first-listed diagnosis increased from 422 000 to 568 000 (NCHS, NHDS). The number of all-listed discharges increased from 6 629 000 to 10 645 000 (NHLBI, unpublished data from the NHDS, 2007).
- Data from ambulatory medical care utilization estimates for 2007 showed that the number of visits for essential hypertension was 46 284 000.<sup>27</sup>
- In 2007, there were 349 000 hospitalizations with a first-listed diagnosis of essential hypertension (ICD-9-CM code 401), but essential hypertension was listed as either a primary or a secondary diagnosis 8 784 000 times for hospitalized inpatients (NHLBI, unpublished data from the NHDS, 2007).

### Awareness, Treatment, and Control

- Data from NHANES/NCHS 2005 to 2008 showed that of those with hypertension who were  $\geq 20$  years of age, 79.6%

were aware of their condition, 70.9% were under current treatment, 47.8% had their hypertension under control, and 52.2% did not have it controlled (NHLBI tabulation, NCHS, NHANES data).

- Data from NHANES 1999 to 2006 showed that 11.2% of adults  $\geq 20$  years of age had treated and controlled BP levels.<sup>28</sup>
- Analysis of NHANES/NCHS data from 1999 to 2004 through 2005 to 2006 found that there were substantial increases in awareness and treatment rates of hypertension. The control rates increased in both sexes, in non-Hispanic blacks, and in Mexican Americans. Among the group  $\geq 60$  years of age, awareness, treatment, and control rates of hypertension increased significantly.<sup>5,29</sup>
- In NHANES/NCHS 2005 to 2006, rates of control were lower in Mexican Americans (35.2%) than in non-Hispanic whites (46.1%) and non-Hispanic blacks (46.5%).<sup>5</sup>
- The awareness, treatment, and control of HBP among those  $\geq 65$  years of age in the CHS/NHLBI improved during the 1990s. The percentages of those aware of and treated for HBP were higher among blacks than among whites. Prevalences with HBP under control were similar. For both groups combined, the control of BP to  $<140/90$  mm Hg increased from 37% in 1990 to 49% in 1999. Improved control was achieved by an increase in antihypertensive medications per person and by an increase in the proportion of the CHS population treated for hypertension from 34.5% to 51.1%.<sup>30</sup>
- Data from the FHS of the NHLBI show that:
  - Among those  $\geq 80$  years of age, only 38% of men and 23% of women had BPs that met targets set forth in the National High Blood Pressure Education Program's clinical guidelines. Control rates in men  $<60$ , 60 to 79, and  $\geq 80$  years of age were 38%, 36%, and 38%, respectively; for women in the same age groups, they were 38%, 28%, and 23%, respectively.<sup>31</sup>
- Data from the Women's Health Initiative Observational Study of nearly 100 000 postmenopausal women across the country enrolled between 1994 and 1998 indicate that although prevalence rates ranged from 27% of women 50 to 59 years of age to 41% of women 60 to 69 years of age to 53% of women 70 to 79 years of age, treatment rates were similar across age groups: 64%, 65%, and 63%, respectively. Despite similar treatment rates, hypertension control is especially poor in older women, with only 29% of hypertensive women 70 to 79 years of age having clinic BPs  $<140/90$  mm Hg compared with 41% and 37% of those 50 to 59 and 60 to 69 years of age, respectively.<sup>32</sup>
- A study of  $>300$  women in Wisconsin showed a need for significant improvement in BP and LDL levels. Of the screened participants, 35% were not at BP goal, 32.4% were not at LDL goal, and 53.5% were not at both goals.<sup>33</sup>
- In 2005, a survey of people in 20 states conducted by the BRFSS of the CDC found that 19.4% of respondents had been told on 2 or more visits to a health professional that they had HBP. Of these, 70.9% reported changing their eating habits; 79.5% reduced the use of or were not using

salt; 79.2% reduced the use of or eliminated alcohol; 68.8% were exercising; and 73.4% were taking antihypertensive medication.<sup>34</sup>

- On the basis of NHANES 2003 to 2004 data, it was found that nearly three fourths of adults with CVD comorbidities have hypertension. Poor control rates of systolic hypertension remain a principal problem that further compromises their already high CVD risk.<sup>35</sup>

### Cost

- The estimated direct and indirect cost of HBP for 2007 is \$43.5 billion (MEPS, NHLBI tabulation).

### Prehypertension

- Prehypertension is untreated SBP of 120 to 139 mm Hg or untreated DBP of 80 to 89 mm Hg and not having been told on 2 occasions by a physician or other health professional that one has hypertension.
- Data from NHANES 1999 to 2006 estimate 29.7% of adults  $\geq 20$  years of age have prehypertension.<sup>28</sup>
- Follow-up of 9845 men and women in the FHS/NHLBI who attended examinations from 1978 to 1994 revealed that at 35 to 64 years of age, the 4-year incidence of hypertension was 5.3% for those with baseline BP <120/80 mm Hg, 17.6% for those with SBP of 120 to 129 mm Hg or DBP of 80 to 84 mm Hg, and 37.3% for those with SBP of 130 to 139 mm Hg or DBP of 85 to 89 mm Hg. At 65 to 94 years of age, the 4-year incidences of hypertension were 16.0%, 25.5%, and 49.5% for these BP categories, respectively.<sup>36</sup>
- Data from FHS/NHLBI also reveal that prehypertension is associated with elevated relative and absolute risks for CVD outcomes across the age spectrum. Compared with normal BP (<120/80 mm Hg), prehypertension was associated with a 1.5- to 2-fold risk for major CVD events in those <60, 60 to 79, and  $\geq 80$  years of age. Absolute risks for major CVD associated with prehypertension increased markedly with age: 6-year event rates for major CVD were 1.5% in prehypertensive people <60 years of age, 4.9% in those 60 to 79 years of age, and 19.8% in those  $\geq 80$  years of age.<sup>31</sup>
- In a study of NHANES 1999 to 2000 (NCHS), people with prehypertension were more likely than those with normal BP levels to have above-normal cholesterol levels, overweight/obesity, and DM, whereas the probability of currently smoking was lower. People with prehypertension were 1.65 times more likely to have 1 or more of these adverse risk factors than were those with normal BP.<sup>37</sup>

Ellipses (...) indicate data not available; NH indicates non-Hispanic.

\*Mortality data are for whites and blacks and include Hispanics.

†These percentages represent the portion of total high blood pressure mortality that is for males versus females.

‡National Health Interview Survey (2009), National Center for Health Statistics; data are weighted percentages for Americans  $\geq 18$  years of age. Data derived from Pleis et al.<sup>16</sup>

Sources: Prevalence: National Health and Nutrition Examination Survey (2005–2008, National Center for Health Statistics) and National Heart, Lung, and Blood Institute. Percentages for racial/ethnic groups are age-adjusted for Americans  $\geq 20$  years of age. Age-specific percentages are extrapolated to the 2008 US population estimates. Mortality: National Center for Health Statistics. These data represent underlying cause of death only. Hospital discharges: National Hospital Discharge Survey, National Center for Health Statistics; data include those discharged alive, dead, or status unknown.

Cost: Medical Expenditure Panel Survey data include estimated direct costs for 2007; indirect costs calculated by National Heart, Lung, and Blood Institute for 2007.

Hypertension is defined in terms of National Health and Nutrition Examination Survey blood pressure measurements and health interviews. A subject was considered hypertensive if systolic blood pressure  $\geq 140$  mm Hg or diastolic blood pressure  $\geq 90$ , said "yes" to taking antihypertensive medication, or was told on 2 occasions of having hypertension.

**Table 7-2. Hypertension Awareness, Treatment, and Control: NHANES 1988–1994 and 1999–2008, by Race and Sex**

	Awareness, %		Treatment, %		Control, %	
	1988–1994	1999–2008	1988–1994	1999–2008	1988–1994	1999–2008
NH white males	63.0	73.5	46.2	63.8	22.0	44.1
NH white females	74.7	78.2	61.6	70.0	32.2	42.7
NH black males	62.5	70.8	42.3	60.3	16.6	35.2

## 8. Congenital Cardiovascular Defects

ICD-9 745 to 747, ICD-10 Q20 to Q28. See Tables 8-1 through 8-4.

Congenital cardiovascular defects, also known as congenital heart defects, are structural problems that arise from abnormal formation of the heart or major blood vessels. ICD-9 lists 25 congenital heart defects codes, of which 21 designate specified anatomic and/or hemodynamic lesions.

Defects range in severity from tiny pinholes between chambers, which are nearly irrelevant and often resolve spontaneously, to major malformations that can require multiple surgical procedures before school age and may result in death in utero, in infancy, or in childhood. The common complex defects include:

- Tetralogy of Fallot (TOF; 9% to 14%)
- Transposition of the great arteries (TGA; 10% to 11%)
- Atrioventricular septal defects (4% to 10%)
- Coarctation of the aorta (8% to 11%)
- Hypoplastic left heart syndrome (HPLHS; 4% to 8%)
- Ventricular septal defects (VSDs)

Although VSDs may close spontaneously, these lesions are the most prevalent in childhood and still account for 14% to 16% of defects that require an invasive procedure within the first year of life.<sup>1</sup> Atrial septal defects (ASDs) are the most common defects seen in adults.<sup>2</sup>

### Prevalence

The estimated number of adults with congenital heart defects ranges from 650 000 to 1.3 million.<sup>1,2</sup> From 1940 to 2002, ≈2 million patients with congenital cardiovascular defects were born in the United States, ≈1 million with simple lesions and 0.5 million each with moderate and complex lesions. Using available data to estimate the prevalence of congenital cardiovascular defects at birth and in adults in the year 2000, the survival of these patients is estimated to be 2000 assuming no treatment (the low estimate) and full treatment (the high estimate). If all were treated, there would be 750 000 survivors with simple lesions, 400 000 with moderate lesions, and 180 000 with complex lesions; in addition, there would be

3 million subjects alive with bicuspid aortic valves. Without treatment, the number of survivors in each group would be 400 000, 220 000, and 30 000, respectively. The actual numbers surviving are projected to be between these 2 sets of estimates.<sup>2</sup> The 32nd Bethesda Conference estimated that the total number of adults living with congenital heart disease in the United States in 2000 was 787 800.<sup>3</sup> In the United States, 1 in 150 adults is expected to have some form of congenital heart disease.<sup>4</sup>

Currently, no measured data are available in the United States for the prevalence of congenital cardiovascular defects in adults. Population data from Quebec, Canada, measured a prevalence of congenital cardiac defects of 11.89 per 1000 children and 4.09 per 1000 adults.<sup>5</sup> The most common types of defects in children are as follows: VSD, 620 000 people; ASD, 235 000 people; valvular pulmonary stenosis, 185 000 people; and patent ductus arteriosus, 173 000 people.<sup>2</sup> The most common lesions seen in adults are ASD and TOF.<sup>3</sup>

### Incidence

As of 2002, the most commonly reported incidence of congenital cardiovascular defects in the United States is between 4 and 10 per 1000, clustering around 8 per 1000 live births.<sup>6</sup> Major defects are usually apparent in the neonatal period, but minor defects may not be detected until adulthood. Thus, true measures of the incidence of congenital heart disease would need to record new cases of defects that present any time in fetal life through adulthood; however, estimates are available only for new cases detected between birth and 30 days of life, known as birth prevalence, or for new cases detected in the first year of life only. Both of these are typically reported as cases per 1000 live births per year and do not distinguish between tiny defects that resolve without treatment and major malformations. To distinguish more serious defects, some studies also report new cases of sufficient severity to require an invasive procedure or that result in death within the first year of life. Despite the absence of a true incidence figure, some data are available and are provided in Table 8-1.

- According to the CDC, 1 in every 110 infants in the metropolitan Atlanta, GA, area is born with a congenital heart defect, including some infants with tiny defects that resolve without treatment. Some defects occur more commonly in boys or girls or in whites or blacks.<sup>6</sup>
- Eight (8.0) defects per 1000 live births, or 36 000 affected infants per year, are expected in the United States. Of these, several studies suggest that 9200, or 2.3 per 1000 live births, require invasive treatment or result in death in the first year of life.<sup>1</sup>
- Estimates also are available for bicuspid aortic valves, which occur in 13.7 per 1000 people; these defects may not require treatment in infancy but can cause problems later in adulthood.<sup>7</sup>
- Some studies suggest that as many as 5% of newborns, or 200 000 per year, are born with tiny muscular VSDs, almost all of which close spontaneously.<sup>8,9</sup> These defects almost never require treatment, so they are not included in Table 8-1.

### Abbreviations Used in Chapter 8

ASD	atrial septal defect
CDC	Centers for Disease Control and Prevention
CHD	coronary heart disease
CI	confidence interval
DM	diabetes mellitus
HPLHS	hypoplastic left heart syndrome
ICD	<i>International Classification of Diseases</i>
KID	Kids' Inpatient Database
NCHS	National Center for Health Statistics
NHLBI	National Heart, Lung, and Blood Institute
TGA	transposition of the great arteries
TOF	tetralogy of Fallot
VSD	ventricular septal defect

- Data collected by the National Birth Defects Prevention Network from 11 states from 1999 to 2001 showed the average prevalence of 18 selected major birth defects. These data indicated that there are >6500 estimated annual cases of 5 cardiovascular defects: truncus arteriosus, TGA, TOF, atrioventricular septal defect, and HPLHS.<sup>10</sup>

### Risk Factors

- Numerous intrinsic and extrinsic nongenetic risk factors contribute to CHD.<sup>11</sup>
- Attributable risks or fractions have been shown to include paternal anesthesia in TOF (3.6%), sympathomimetic medication for coarctation of the aorta (5.8%), pesticides for VSD (5.5%), and solvents for HPLHS (4.6%).<sup>12</sup>
- A study of infants born with heart defects unrelated to genetic syndromes who were included in the National Birth Defects Prevention Study found that women who reported smoking in the month before becoming pregnant or in the first trimester were more likely to give birth to a child with a septal defect. Compared with the infants of mothers who did not smoke during pregnancy, infants of mothers who were heavy smokers ( $\geq 25$  cigarettes daily) were twice as likely to have a septal defect.<sup>13</sup>
- Associations between exposure to air pollutants during first-trimester pregnancy and risks of congenital heart defects were documented from 1986 to 2003 by the Metropolitan Atlanta Congenital Defects Program that related carbon monoxide, nitrogen dioxide, and sulfur dioxide measurements to the risk of ASD, VSD, TGA, and TOF.<sup>14</sup>
- The results of a population-based study examining pregnancy obesity found a weak to moderate positive association of maternal obesity with 7 of 16 categories of birth defects.<sup>15</sup>
- Although folic acid supplementation is recommended during pregnancy to potentially reduce the risk of congenital heart defects,<sup>11</sup> there has been only 1 US population-based case-control study, performed with the Baltimore-Washington Infant Study between 1981 and 1989, that showed an inverse relationship between folic acid use and the risk of TGA.<sup>16</sup> A study from Quebec that analyzed 1.3 million births from 1990 to 2005 found a significant 6%/y reduction in severe congenital heart defects using a time-trend analysis before and after public health measures were instituted that mandated folic acid fortification of grain and flour products in Canada.<sup>17</sup>
- Pregestational DM was significantly associated with cardiac defects, both isolated and multiple. Gestational DM was associated with a limited group of birth defects.<sup>18</sup>

### Mortality

Congenital cardiovascular defects mortality in 2007 was 3547. Any-mention mortality related to congenital cardiovascular defects in 2007 was 5643.

- Congenital cardiovascular defects are the most common cause of infant death resulting from birth defects; >24% of infants who die of a birth defect have a heart defect.<sup>19</sup>

- The 2007 death rate for congenital cardiovascular defects was 1.2. Death rates were 1.3 for white males, 1.5 for black males, 1.0 for white females, and 1.4 for black females. Crude infant mortality rates (<1 year of age) were 35.5 for white infants and 51.7 for black infants.<sup>20</sup>
- In 2007, 189 000 life-years were lost before 55 years of age because of deaths resulting from congenital cardiovascular defects. This is almost as many as the life-years lost from leukemia and asthma combined (NHLBI tabulation of NCHS mortality data).
- The mortality rate attributable to congenital defects has been declining. From 1979 to 1997, age-adjusted death rates resulting from all defects declined 39%, and deaths tended to occur at progressively older ages. Nevertheless, 45% of deaths still occurred in infants <1 year of age. The mortality rate varies considerably according to type of defect.<sup>21</sup>
- From 1997 to 2007, death rates for congenital cardiovascular defects declined 33.3%, whereas the actual number of deaths declined 23.8%.<sup>19</sup>
- Data from the Pediatric Heart Network conducted in 15 North American centers revealed that even in lesions associated with the highest mortality among congenital lesions such as HPLHS, aggressive palliation can lead to 12-month survival from 64% to 74%.<sup>22</sup>
- Data analysis from the Society of Thoracic Surgeons, a voluntary registry with self-reported data for a 4-year cycle (2004 to 2007) from 68 centers performing congenital heart surgery (67 from the United States and 1 from Canada), showed that of 61 410 total operations, the overall aggregate hospital discharge mortality rate was 3.7%; specifically, for neonates (0 to 30 days of age), the mortality rate was 10.7%; for infants (31 days to 1 year of age), it was 2.6%; for children (>1 year to 18 years of age), it was 1.2%; and for adults (>18 years of age), it was 1.9%.<sup>23</sup>
- Using the Nationwide Inpatient Sample 1988 to 2003, mortality was examined for 12 congenital heart defects procedures. A total of 30 250 operations were identified, which yielded a national estimate of  $152\,277 \pm 7875$  operations. Of these, 27% were performed in patients  $\geq 18$  years of age. The overall in-hospital mortality rate for adult patients with congenital heart defects was 4.71% (95% CI, 4.19 to 5.23), with a significant reduction in mortality observed when surgery was performed on adult patients with congenital heart defects by pediatric versus nonpediatric heart surgeons (1.87% versus 4.84%;  $P < 0.0001$ ).<sup>24</sup>

### Hospitalizations

In 2004, birth defects accounted for >139 000 hospitalizations, representing 47.4 stays per 100 000 people. Cardiac and circulatory congenital anomalies, which include ASDs and VSDs, accounted for more than one third of all hospital stays for birth defects and had the highest in-hospital mortality rate. Between 1997 and 2004, hospitalization rates increased by 28.5% for cardiac and circulatory congenital anomalies. For almost 86 300 hospitalizations, ASD was noted as the principal reason for the hospital stay or as a coexisting or secondary condition.<sup>25</sup>

## Cost

- From 2003 data from the Healthcare Cost and Utilization Project 2003 Kids' Inpatient Database (KID) and information on birth defects in the Congenital Malformations Surveillance Report, it was found that the most expensive average neonatal hospital charges were for 2 congenital heart defects: HPLHS (\$199 597) and common truncus arteriosus (\$192 781). Two other cardiac defects, coarctation of the aorta and TGA, were associated with average hospital charges in excess of \$150 000. For the 11 selected cardiovascular congenital defects (of 35 birth defects considered), there were 11 578 hospitalizations in 2003 and 1550 in-hospital deaths (13.4%). Estimated total hospital charges for these 11 conditions were \$1.4 billion.<sup>26</sup>
- In 2004, hospital costs for congenital cardiovascular defect conditions totaled \$2.6 billion. The highest aggregate costs were for stays related to cardiac and circulatory congenital anomalies, which accounted for ≈\$1.4 billion, more than half of all hospital costs for birth defects.<sup>25</sup>

**Table 8-1. Congenital Cardiovascular Defects**

Population Group	Estimated Prevalence, Adults	Mortality, 2007, All Ages	Hospital Discharges, 2007, All Ages
Both sexes	650 000 to 1.3 million <sup>2</sup>	3547	67 000
Males	...	1935 (54.6%)*	31 000
Females	...	1612 (45.4%)*	36 000
NH white males	...	1506	...
NH white females	...	1226	...
NH black males	...	341	...
NH black females	...	309	...

Ellipses (...) indicate data not available; NH, non-Hispanic.

\*These percentages represent the portion of total congenital cardiovascular mortality that is for males versus females.

Sources: Mortality: National Center for Health Statistics. These data represent underlying cause of death only; data for white and black males and females include Hispanics. Hospital discharges: National Hospital Discharge Survey, National Center for Health Statistics; data include those inpatients discharged alive, dead, or status unknown.

**Table 8-2. Annual Incidence of Congenital Cardiovascular Defects<sup>1,6-9,27</sup>**

Type of Presentation	Rate per 1000 Live Births	
		n
Fetal loss	Unknown	Unknown
Invasive procedure during the first year	2.3	9200
Detected during first year*	9	36 000
Bicuspid aortic valve	13.7	54 800
Other defects detected after first year	Unknown	Unknown
Total	Unknown	Unknown

\*Includes stillbirths and pregnancy termination at <20 weeks' gestation; includes some defects that resolve spontaneously or do not require treatment.

**Table 8-3. Estimated Prevalence of Congenital Cardiovascular Defects and Percent Distribution by Type, United States, 2002\* (in Thousands)**

Type	Prevalence, n			Percent of Total		
	Total	Children	Adults	Total	Children	Adults
Total	994	463	526	100	100	100
VSD†	199	93	106	20.1	20.1	20.1
ASD	187	78	109	18.8	16.8	20.6
Patent ductus arteriosus	144	58	86	14.2	12.4	16.3
Valvular pulmonic stenosis	134	58	76	13.5	12.6	14.4
Coarctation of aorta	76	31	44	7.6	6.8	8.4
Valvular aortic stenosis	54	25	28	5.4	5.5	5.2
TOF	61	32	28	6.1	7	5.4
Atrioventricular septal defect	31	18	13	3.1	3.9	2.5
TGA	26	17	9	2.6	3.6	1.8
Hypoplastic right heart syndrome	22	12	10	2.2	2.5	1.9
Double-outlet right ventricle	9	9	0	0.9	1.9	0.1
Single ventricle	8	6	2	0.8	1.4	0.3
Anomalous pulmonary venous connection	9	5	3	0.9	1.2	0.6
Truncus arteriosus	9	6	2	0.7	1.3	0.5
HPLHS	3	3	0	0.3	0.7	0
Other	22	12	10	2.1	2.6	1.9

VSD indicates ventricular septal defect; ASD, atrial septal defect; TOF, tetralogy of Fallot; TGA, transposition of the great arteries; HPLHS, hypoplastic left heart syndrome.

\*Excludes an estimated 3 million bicuspid aortic valve prevalence (2 million in adults and 1 million in children).

†Small VSD, 117 000 (65 000 adults and 52 000 children); large VSD, 82 000 (41 000 adults and 41 000 children).

**Table 8-4. Surgery for Congenital Heart Disease**

	Sample	Population, Weighted
Surgery for congenital heart disease, n	14 888	25 831
Deaths, n	736	1253
Mortality rate, %	4.9	4.8
By sex (81 missing in sample)		
Males	8127	14 109
Deaths, n	420	714
Mortality rate, %	5.2	5.1
Females	6680	11 592
Deaths, n	315	539
Mortality rate, %	4.7	4.6
By type of surgery		
ASD secundum surgery, n	834	1448
Deaths, n	3	6
Mortality rate, %	0.4	0.4
Norwood procedure for HPLHS, n	161	286
Deaths, n	42	72
Mortality rate, %	26.1	25.2

ASD indicates atrial septal defect; HPLHS, hypoplastic left heart syndrome.

In 2003, 25 000 cardiovascular operations for congenital cardiovascular defects were performed on children <20 years of age. Inpatient mortality rate after all types of cardiac surgery was 4.8%. Nevertheless, mortality risk varies substantially for different defect types, from 0.4% for ASD repair to 25.2% for first-stage palliation for HPLHS. Fifty-five percent of operations were performed in males. In unadjusted analysis, mortality after cardiac surgery was somewhat higher for males than for females (5.1% versus 4.6%).

## 9. Cardiomyopathy and Heart Failure

See Table 9-1 and Charts 9-1 through 9-3.

### Cardiomyopathy

ICD-9 425; ICD-10 I42.

Mortality—24 703. Any-mention mortality—48 579. Hospital discharges—55 000.

- Mortality from cardiomyopathy is highest in older people, men, and blacks.
- Tachycardia-induced cardiomyopathy develops slowly and appears reversible, but recurrent tachycardia causes rapid decline in left ventricular function and development of HF. Sudden death is possible.<sup>1</sup>
- Since 1996, the NHLBI-sponsored Pediatric Cardiomyopathy Registry has collected data on all children with newly diagnosed cardiomyopathy in New England and the Central Southwest (Texas, Oklahoma, and Arkansas).<sup>2</sup>

- The overall incidence of cardiomyopathy is 1.13 cases per 100 000 in children <18 years of age.
- In children <1 year of age, the incidence is 8.34, and in children 1 to 18 years of age, it is 0.70 per 100 000.
- The annual incidence is lower in white than in black children, higher in boys than in girls, and higher in New England (1.44 per 100 000) than in the Central Southwest (0.98 per 100 000).

- Studies show that 36% of young athletes who die suddenly have probable or definite hypertrophic cardiomyopathy.<sup>3</sup>
- Hypertrophic cardiomyopathy is the leading cause of sudden cardiac death in young people, including trained

athletes. Hypertrophic cardiomyopathy is the most common inherited heart defect, occurring in 1 of 500 individuals. In the United States, ≈500 000 people have hypertrophic cardiomyopathy, yet most are unaware of it.<sup>4</sup>

- In a recent report of the Pediatric Cardiomyopathy Registry, the overall annual incidence of hypertrophic cardiomyopathy in children was 4.7 per 1 million children. There was a higher incidence in the New England than in the Central Southwest region, in boys than in girls, and in children diagnosed at <1 year of age than in older children.<sup>5</sup>
- Dilated cardiomyopathy is the most common form of cardiomyopathy. The Pediatric Cardiomyopathy Registry recently reported an annual incidence of dilated cardiomyopathy in children <18 years of age of 0.57 per 100 000 per year overall. The annual incidence was higher in boys than in girls (0.66 versus 0.47 cases per 100 000), in blacks than in whites (0.98 versus 0.46 cases per 100 000), and in infants (<1 year of age) than in children (4.40 versus 0.34 cases per 100 000). The majority of children (66%) had idiopathic disease. The most common known causes were myocarditis (46%) and neuromuscular disease (26%).<sup>6</sup>

### Heart Failure

ICD-9 428, ICD-10 I50.

#### Incidence

- Data from the NHLBI-sponsored FHS<sup>7</sup> indicate that:
  - HF incidence approaches 10 per 1000 population after 65 years of age.
  - Seventy-five percent of HF cases have antecedent hypertension.
  - At 40 years of age, the lifetime risk of developing HF for both men and women is 1 in 5. At 80 years of age, remaining lifetime risk for development of new HF remains at 20% for men and women, even in the face of a much shorter life expectancy.
  - At 40 years of age, the lifetime risk of HF occurring without antecedent MI is 1 in 9 for men and 1 in 6 for women.
  - The lifetime risk for people with BP >160/90 mm Hg is double that of those with BP <140/90 mm Hg.
- The annual rates per 1000 population of new HF events for white men are 15.2 for those 65 to 74 years of age, 31.7 for those 75 to 84 years of age, and 65.2 for those ≥85 years of age. For white women in the same age groups, the rates are 8.2, 19.8, and 45.6, respectively. For black men, the rates are 16.9, 25.5, and 50.6,\* and for black women, the estimated rates are 14.2, 25.5, and 44.0,\* respectively (CHS, NHLBI).<sup>8</sup>
- In MESA, African Americans had the highest risk of developing HF, followed by Hispanic, white, and Chinese Americans (4.6, 3.5, 2.4, and 1.0 per 1000 person-years, respectively). This higher risk reflected differences in the prevalence of hypertension, DM, and socioeconomic status. African Americans had the highest proportion of

\*Unreliable estimate.

incident HF not preceded by clinical myocardial infarction (75%).<sup>9</sup>

- In Olmsted County, MN, the incidence of HF did not decline between 1979 and 2000.<sup>10</sup>
- In the ARIC study of the NHLBI, the age-adjusted incidence rate per 1000 person-years was 3.4 for white women, less than all other groups—that is, white men (6.0), black women (8.1), and black men (9.1). The 30-day, 1-year, and 5-year case fatality rates after hospitalization for HF were 10.4%, 22%, and 42.3%, respectively. Blacks had a greater 5-year case fatality rate than whites ( $P<0.05$ ). HF incidence rates in black women were more similar to those of men than of white women. The greater HF incidence in blacks than in whites is explained largely by blacks' greater levels of atherosclerotic risk factors.<sup>11</sup>
- Data from Kaiser Permanente indicated an increase in the incidence of HF among the elderly, with the effect being greater in men.<sup>12</sup>
- Data from hospitals in Worcester, MA, indicate that during 2000, the incidence and attack rates for HF were 219 per 100 000 and 897 per 100 000, respectively. HF was more frequent in women and the elderly. The hospital fatality rate was 5.1%.<sup>13</sup>
- In the CARDIA study, HF before 50 years of age is more common among blacks than whites. Hypertension, obesity, and systolic dysfunction are important risk factors that may be targets for prevention.<sup>14</sup>

#### **Risk Factors**

- In the NHLBI-sponsored FHS, hypertension is a common risk factor for HF followed closely by antecedent MI.<sup>15</sup>
- In a study of 2763 postmenopausal women with coronary disease, DM was the strongest risk factor for HF.<sup>16</sup>
- The prevalence of DM is increasing among older people with HF. Between 1979 and 1999, among subjects in Olmsted County, MN, with a first diagnosis of HF, the prevalence of DM increased 3.8% every year. The odds of having DM for those first diagnosed with HF in 1999 were nearly 4 times higher than for those diagnosed 20 years earlier.<sup>17</sup>
- In the Framingham Offspring Study, among 2739 participants, increased circulating concentrations of resistin were associated with incident HF, independently of prevalent coronary disease, obesity, insulin resistance, and inflammation.<sup>18</sup>
- Among 20 900 male physicians in the Physicians Health Study, the lifetime risk of HF at 40 years of age was 13.8%. Lifetime risk of HF was higher in men with hypertension; healthy lifestyle factors (normal weight, not smoking, regular exercise, moderate alcohol intake, consumption of breakfast cereals, and consumption of fruits and vegetables) were related to lower risk of HF.<sup>19</sup>
- Among 2934 participants in the Health Aging, Body and Composition (ABC) study, the incidence of HF was 13.6 per 1000 person-years. Men and black participants were more likely to develop HF. Coronary disease (population-attributable risk [PAR], 23.9% for white participants, 29.5% for black participants) and uncontrolled BP (PAR, 21.3% for white participants, 30.1% for black participants) had the highest PARs in both races. There was a higher

overall proportion of HF attributable to modifiable risk factors in black participants versus white participants (67.8% versus 48.9%). Hospitalizations were higher among black participants.<sup>20</sup>

#### **Left Ventricular Function**

- Data from Olmsted County, MN, indicate that:
  - Among asymptomatic individuals, the prevalence of left ventricular diastolic dysfunction was 21% for mild diastolic dysfunction and 7% for moderate or severe diastolic dysfunction. The prevalence of systolic dysfunction was 6%. The presence of any left ventricular dysfunction (systolic or diastolic) was associated with an increased risk of developing overt HF, and diastolic dysfunction was predictive of all-cause death.<sup>21</sup>
  - Among individuals with symptomatic HF, the prevalence of left ventricular diastolic dysfunction was 6% for mild diastolic dysfunction and 75% for moderate or severe diastolic dysfunction.<sup>22</sup> The proportion of people with HF and preserved ejection fraction (EF) increased over time. Survival improved over time among individuals with reduced EF but not among those with preserved EF.<sup>23</sup>

#### **Mortality**

- In 2007, HF any-mention mortality was 277 193 (121 684 males and 155 509 females). HF was mentioned on 277 193 US death certificates and was the underlying cause in 56 565 of those deaths in 2007 (NCHS, NHLBI). Table 9-1 contains the numbers of these deaths that are coded for HF as the underlying cause.
- The 2007 overall any-mention death rate for HF was 85.4. Any-mention death rates were 99.2 for white males, 104.2 for black males, 76.7 for white females, and 82.5 for black females (NCHS, NHLBI).
- One in 9 deaths has HF mentioned on the death certificate (NCHS, NHLBI).
- The number of any-mention deaths from HF was about as high in 1995 (287 000) as it was in 2006 (283 000) (NCHS, NHLBI).
- Survival after HF diagnosis has improved over time as shown by data from the FHS<sup>24</sup> and Olmsted County Study.<sup>10</sup> However, the death rate remains high: ≈50% of people diagnosed with HF will die within 5 years.<sup>10,24</sup>
- In the elderly, data from Kaiser Permanente indicate that survival after the onset of HF also improved.<sup>12</sup>

#### **Hospital Discharges/Ambulatory Care Visits**

- Hospital discharges for HF were essentially unchanged from 1997 to 2007 with first listed discharges of 966 000 and 990 000, respectively (unpublished data from the NHDS 2007, NCHS, NHLBI).
- Data from Ambulatory Medical Care Utilization Estimates for 2007 showed that the number of visits for HF was 3 434 000.<sup>25</sup>
- Among 1077 patients with HF in Olmsted County, MN, hospitalizations were common after HF diagnosis, with

83% patients hospitalized at least once and 43% hospitalized at least 4 times. More than one half of hospitalizations were related to noncardiovascular causes.<sup>26</sup>

## 10. Other Cardiovascular Diseases

See Table 10-1.

Mortality and any-mention mortality in this section are for 2007. “Mortality” is the number of deaths in 2007 for the given underlying cause. Prevalence data are for 2006. Hospital discharge data are from the NHDS/NCHS; data include inpatients discharged alive, dead, or status unknown. Hospital discharge data for 2007 are based on ICD-9 codes.

### Abbreviations Used in Chapter 10

AAA	abdominal aortic aneurysm
ABI	ankle brachial index
AF	atrial fibrillation
AHA	American Heart Association
ARIC	Atherosclerosis Risk In Communities
BMI	body mass index
CAD	coronary artery disease
CARDIA	Coronary Artery Risk Development in Young Adults
CDC	Centers for Disease Control and Prevention
CHD	coronary heart disease
CHS	Cardiovascular Health Study
CI	confidence interval
CT	computed tomography
CTEPH	chronic thromboembolic pulmonary hypertension
CVD	cardiovascular disease
DM	diabetes mellitus
DVT	deep vein thrombosis
FHS	Framingham Heart Study
HD	heart disease
HF	heart failure
HLA	human leukocyte antigen
HR	hazard ratio
ICD-9	<i>International Classification of Diseases, 9th Revision</i>
ICD-10	<i>International Classification of Diseases, 10th Revision</i>
IE	infective endocarditis
KD	Kawasaki disease
MESA	Multi-Ethnic Study of Atherosclerosis
MI	myocardial infarction
NCHS	National Center for Health Statistics
NHANES	National Health and Nutrition Examination Survey
NHDS	National Hospital Discharge Survey
NHLBI	National Heart, Lung, and Blood Institute
OR	odds ratio
PAD	peripheral arterial disease
PE	pulmonary embolism
REACH	Reduction of Atherothrombosis for Continued Health
RR	relative risk
VF	ventricular fibrillation
VSS	venous stasis syndrome
VTE	venous thromboembolism

### Valvular Heart Disease

ICD-9 424; ICD-10 I34 to I38.

Mortality—23 313. Any-mention mortality—44 149. Hospital discharges—98 000.

- Echocardiographic data from the CARDIA Study (n=4351), the ARIC Study (n=2435), and the CHS (n=5125) were pooled to assess the prevalence of valve disease. The prevalence increased with age, from 0.7% (95% CI 0.5% to 1.0%) in participants 18 to 44 years of age to 13.3% (95% CI 11.7% to 15.0%) in participants  $\geq 75$  years of age ( $P < 0.0001$ ). The prevalence of valve disease, adjusted to the US 2000 population, was 2.5% (95% CI 2.2% to 2.7%). The adjusted mortality risk ratio associated with valve disease was 1.36 (95% CI 1.15 to 1.62;  $P = 0.0005$ ).<sup>1</sup>
- Doppler echocardiography data in 1696 men and 1893 women ( $54 \pm 10$  years of age) attending a routine examination at the Framingham Study were used to assess the prevalence of valvular regurgitation. Mitral regurgitation and tricuspid regurgitation of more than or equal to mild severity were seen in 19.0% and 14.8% of men and 19.1% and 18.4% of women, respectively. Aortic regurgitation of more than or equal to trace severity was present in 13.0% of men and 8.5% of women.<sup>2</sup>

### Aortic Valve Disorders

ICD-9 424.1; ICD-10 I35.

Mortality—15 183. Any-mention mortality—28 191. Hospital discharges—48 000.

- Calcific aortic stenosis on a trileaflet valve or bicuspid aortic valve is the most common cause of aortic stenosis.<sup>3</sup>
- In the MESA, a study of 5880 participants 45 to 84 years of age, aortic valve calcium was quantified with serial CT images. During a mean follow-up of 2.4 years, 210 subjects (4.1%) had a mean incidence rate of progression of 1.7% per year, which increased significantly with age. The incident aortic valve calcium risk was associated with several traditional cardiovascular risk factors, specifically age, male sex, BMI, and smoking.<sup>4</sup>
- In the Euro Heart Survey, which included 4910 patients in more than 25 countries, aortic stenosis was the most frequent lesion, accounting for 43% of all patients who had valvular heart disease.<sup>5</sup>
- Among men and women  $\geq 65$  years of age enrolled in the CHS who underwent echocardiography, the aortic valve was normal in 70% of cases, sclerotic without outflow obstruction in 29%, and stenotic in 2%. Aortic sclerosis was associated with an increase of  $\approx 50\%$  in the risk of death due to cardiovascular causes and the risk of MI.<sup>6</sup> Clinical factors associated with aortic sclerosis and stenosis were similar to risk factors for atherosclerosis.<sup>7</sup> These data largely exclude patients with congenital heart disease, a group that is expected to increasingly contribute to the prevalence of valve disease.

### Mitral Valve Disorders

ICD-9 424.0; ICD-10 I34.

Mortality—2644. Any-mention mortality—5608. Hospital discharges—42 000.

**Prevalence**

- In pooled data from the CARDIA, ARIC, and CHS studies, mitral valve disease was the most common valvular lesion. At least moderate mitral regurgitation occurred at a frequency of 1.7% as adjusted to the US adult population of 2000, increasing from 0.5% to 9.3% between 18 and  $\geq 75$  years of age.<sup>1</sup>
- Isolated mitral stenosis is more common in women and occurs in 40% of all patients presenting with rheumatic HD.<sup>8</sup>
- The NHLBI-sponsored FHS reports that among people 26 to 84 years of age, the prevalence of mitral valve disorders is  $\approx 1\%$  to  $2\%$  and equal between women and men.<sup>9</sup>
- The prevalence of mitral valve prolapse in the general population was evaluated with the use of echocardiograms of 1845 women and 1646 men who participated in the fifth examination of the Offspring Cohort of the FHS. The prevalence of mitral valve prolapse was 2.4%. The frequencies of chest pain, dyspnea, and electrocardiographic abnormalities were similar among subjects with prolapse and those without prolapse.<sup>9</sup>

**Pulmonary Valve Disorders**

ICD-9 424.3; ICD-10 I37.

Mortality—15. Any-mention mortality—43.

**Tricuspid Valve Disorders**

ICD-9 424.2; ICD-10 I36.

Mortality—23. Any-mention mortality—97.

**Rheumatic Fever/Rheumatic HD**

ICD-9 390 to 398; ICD-10 I00 to I09.

Mortality—3201. Any-mention mortality—5838.

- The incidence of acute rheumatic fever has decreased in the United States.<sup>10</sup>
- Although localized outbreaks have occurred, the overall incidence of acute rheumatic fever remains very low in most areas of the United States.<sup>11,12</sup>
- The incidence of rheumatic fever remains high in blacks, Puerto Ricans, Mexican Americans, and American Indians.<sup>13</sup>
- In 1950,  $\approx 15\,000$  Americans (adjusted for changes in ICD codes) died of rheumatic fever/rheumatic HD compared with  $\approx 3300$  today (NCHS/NHLBI).
- From 1996 to 2006, the death rate for rheumatic fever/rheumatic HD fell 8.3%, and actual deaths declined 26.2% (NCHS/NHLBI).
- The 2006 overall death rate for rheumatic fever/rheumatic HD was 1.1. Death rates were 0.8 for white males, 0.7 for black males, 1.3 for white females, and 0.9 for black females (NCHS/NHLBI).
- Immune risk factors have been linked with rheumatic HD. Human leukocyte antigen (HLA) typing was performed in 120 black patients with severe chronic rheumatic HD requiring cardiac surgery; the HLA-DR 1 antigen was present in 12.6% of patients compared with 2.7% of normal control subjects, and the HLA-DRw6 antigen was present in 31.1% of patients compared with 15% of control subjects, which suggests that genetically determined immune response factors may play a role in the pathogenesis of severe chronic rheumatic HD.<sup>14</sup>

**Bacterial Endocarditis**

ICD-9 421.0; ICD-10 I33.0.

Any-mention mortality—2419. Hospital discharges—27 000, primary plus secondary diagnoses.

- The 2007 AHA Guidelines on Prevention of Infective Endocarditis<sup>15</sup> state that infective endocarditis (IE) is thought to result from the following sequence of events: (1) Formation of nonbacterial thrombotic endocarditis on the surface of a cardiac valve or elsewhere that endothelial damage occurs; (2) bacteremia; and (3) adherence of the bacteria in the bloodstream to nonbacterial thrombotic endocarditis and proliferation of bacteria within a vegetation. Viridans group streptococci are part of the normal skin, oral, respiratory, and gastrointestinal tract flora, and they cause  $\geq 50\%$  of cases of community-acquired native-valve IE not associated with intravenous drug use.<sup>16</sup>
- Transient bacteremia is common with manipulation of the teeth and periodontal tissues, and reported frequencies of bacteremia because of dental procedures vary widely: Tooth extraction, 10% to 100%; periodontal surgery, 36% to 88%; scaling and root planing, 8% to 80%; teeth cleaning, up to 40%; rubber dam matrix/wedge placement, 9% to 32%; and endodontic procedures, up to 20%. Transient bacteremia also occurs frequently during routine daily activities unrelated to dental procedures: Tooth brushing and flossing, 20% to 68%; use of wooden toothpicks, 20% to 40%; use of water-irrigation devices, 7% to 50%; and chewing food, 7% to 51%. When it is considered that the average person living in the United States has  $< 2$  dental visits per year, the frequency of bacteremia from routine daily activities is far greater than that associated with dental procedures.<sup>1</sup>
- Although the absolute risk for IE from a dental procedure is impossible to measure precisely, the best available estimates are as follows: If dental treatment causes 1% of all cases of viridans group streptococcal IE annually in the United States, the overall risk in the general population is estimated to be as low as 1 case of IE per 14 million dental procedures. The estimated absolute risk rates for IE from a dental procedure in patients with underlying cardiac conditions are as follows<sup>15</sup>:
  - Mitral valve prolapse: 1 per 1.1 million procedures
  - CHD: 1 per 475 000
  - Rheumatic HD: 1 per 142 000
  - Presence of a prosthetic cardiac valve: 1 per 114 000
  - Previous IE: 1 per 95 000 dental procedures
- Although these calculations of risk are estimates, it is likely that the number of cases of IE that result from a dental procedure is exceedingly small. Therefore, the number of cases that could be prevented by antibiotic prophylaxis, even if prophylaxis were 100% effective, is similarly small. One would not expect antibiotic prophylaxis to be near 100% effective, however, because of the nature of the organisms and choice of antibiotics.<sup>15</sup>

**Endocarditis, Valve Unspecified**

ICD-9 424.9; ICD-10 I38.

Mortality—5448. Any-mention mortality—10 469.

**Kawasaki Disease**

ICD-9 446.1; ICD-10 M30.3.

Mortality—4. Any-mention mortality—7. Hospital discharges—5000 (figure considered unreliable), primary plus secondary diagnoses.

- Kawasaki disease (KD) is more prevalent in the United States than in Japan, where outbreaks occurred in 1979, 1982, and 1986 and where the majority of cases occurred in those under the age of 2 years and predominantly in boys.<sup>17</sup>
- An estimated 4248 hospitalizations for KD occurred in the United States in 2000, with a median patient age of 2 years. Race-specific incidence rates indicate that KD is most common among Americans of Asian and Pacific Island descent (32.5 per 100 000 children <5 years of age), occurs with intermediate frequency in non-Hispanic blacks (16.9 per 100 000 children <5 years of age) and Hispanics (11.1 per 100 000 children <5 years of age), and is least common in whites (9.1 per 100 000 children <5 years of age).<sup>18</sup> In the United States, KD is more common during the winter and early spring months; boys with KD outnumber girls by  $\approx 1.5:1$  to  $1.7:1$ ; and 76% of children with KD are <5 years of age.<sup>19</sup>

### Venous Thromboembolism Epidemiology (Including Deep Vein Thrombosis and Pulmonary Embolism)<sup>20</sup>

#### **Pulmonary Embolism**

ICD-9 415.1; ICD-10 I26.

Mortality—7097. Any-mention mortality—27 824. Hospital discharges—146 000.

#### **Deep Vein Thrombosis**

ICD-9 451.1; ICD-10 I80.2.

Mortality—2381. Any-mention mortality—12 018.

#### **Incidence**

- Venous thromboembolism (VTE) consists of deep vein thrombosis (DVT), which typically involves deep veins of the leg or pelvis, and its complication, pulmonary embolism (PE).
- The average incidence of VTE among whites is 108 per 100 000 person-years, with  $\approx 250$  000 incident cases occurring annually among US whites.
- VTE incidence appears to be similar or higher among African Americans and lower among Asian Americans and Native Americans.
- With adjustment for the different age and sex distributions of African Americans, VTE incidence is  $\approx 78$  per 100 000, which suggests 27 000 incident VTE cases occur annually among US African Americans.
- Modeling suggests that more than 900 000 incident or recurrent VTE events occur annually in the United States, of which approximately one third are fatal.
- VTE incidence has not changed significantly over the last 25 years.
- Incidence rates increase exponentially with age for both males and females for both DVT and PE.

- Incidence rates are higher in women during childbearing years, whereas incidence rates after age 45 years are higher in men.
- PE accounts for an increasing proportion of VTE with increasing age for both sexes.

#### **Survival**

- Observed survival after VTE is significantly worse than expected survival for age and sex, and survival after PE is much worse than after DVT alone.
- For almost one quarter of patients with PE, the initial clinical presentation is sudden death.
- Thirty-day VTE survival is 74.8% (DVT alone, 96.2%; PE with or without DVT, 59.1%).<sup>21</sup>
- PE is an independent predictor of reduced survival for up to 3 months.
- Because most PE deaths are sudden and are usually attributed to underlying disease (eg, cancer; other chronic heart, lung, or renal disease), secular trends in VTE survival are confounded by autopsy rates.

#### **Recurrence**

- VTE is a chronic disease with episodic recurrence;  $\approx 30\%$  of patients develop recurrence within the next 10 years.
- The hazard of recurrence varies with the time since the incident event and is highest within the first 6 to 12 months.
- Independent predictors of recurrence include increasing patient age and BMI; neurological disease with leg paresis; active cancer; lupus anticoagulant or antiphospholipid antibody, antithrombin, protein C, or protein S deficiency; and persistently increased plasma fibrin D-dimer.

#### **Complications**

- VTE complications include venous stasis syndrome (VSS) (or postthrombotic syndrome), venous ulcer, and chronic thromboembolic pulmonary hypertension (CTEPH).
- The 20-year cumulative VSS and venous ulcer incidence after proximal DVT is  $\approx 40\%$  and 3.7%, respectively.
- CTEPH incidence is 6.5 per million person-years;  $\approx 1400$  incident CTEPH cases occur annually among US whites.

#### **Risk Factors**

- Independent VTE risk factors include increasing patient age, surgery, trauma/fracture, hospital or nursing home confinement, active cancer, central vein catheterization or transvenous pacemaker, prior superficial vein thrombosis, varicose veins, and neurological disease with leg paresis, and among women, oral contraceptive use, pregnancy/postpartum status, and hormone therapy.
- Together, these risk factors account for  $>75\%$  of all incident VTE that occurs in the community.
- Compared with residents in the community, hospitalized residents have a  $>130$ -fold higher incidence of VTE (71 versus 9605 cases per 100 000 person-years).<sup>22</sup>
- Hospitalization and nursing home residence together account for almost 60% of incident VTE events that occur in the community.

- Pregnancy-associated VTE incidence is 200 per 100 000 woman-years; compared with nonpregnant women of childbearing age, the RR is increased  $\approx$ 4-fold.
- VTE risk during the postpartum period is  $\approx$ 5-fold higher than during pregnancy.
- VTE is highly heritable and follows a complex mode of inheritance that involves environmental interaction.
- Inherited thrombophilias (eg, inherited antithrombin, protein C, or protein S deficiency; factor V Leiden; prothrombin G20210A; ABO blood type non-O) interact with such clinical risk factors (ie, environmental “exposures”) as oral contraceptives, pregnancy, hormone therapy, and surgery to compound VTE risk.
- Similarly, genetic interaction compounds the risk of incident and recurrent VTE.

### Peripheral Arterial Disease

- Peripheral arterial disease (PAD) affects  $\approx$ 8 million Americans and is associated with significant morbidity and mortality.<sup>23</sup> Prevalence increases dramatically with age, and PAD disproportionately affects blacks.<sup>23</sup>
- PAD affects 12% to 20% of Americans  $\geq$ 65 years of age.<sup>24</sup> Despite its prevalence and cardiovascular risk implications, only  $\approx$ 70% to 80% of patients with PAD undergo recommended antiplatelet therapy or lipid-lowering therapy.<sup>25</sup>
- In the general population, only  $\approx$ 10% of people with PAD have the classic symptom of intermittent claudication. Approximately 40% do not complain of leg pain, whereas the remaining 50% have a variety of leg symptoms different from classic claudication.<sup>26,27</sup> In an older, disabled population of women, however, as many as two thirds of individuals with PAD had no exertional leg symptoms.<sup>28</sup>
- The risk factors for PAD are similar but not identical to those for CHD. DM and cigarette smoking are stronger risk factors for PAD than for CHD.<sup>29</sup> ORs for associations of DM and smoking with symptomatic PAD are  $\approx$ 3.0 to 4.0. Most studies suggest that the prevalence of PAD is similar in men and women.<sup>30</sup>
- Pooled data from 11 studies in 6 countries found that PAD is a marker for systemic atherosclerotic disease. The age- and sex-adjusted RR of all-cause death was 2.35; for CVD mortality, it was 3.34; and for CHD fatal and nonfatal events combined, it was 2.13. The findings for stroke were slightly weaker but still significant, with a pooled RR of 1.86 for fatal and nonfatal events combined.<sup>31</sup>
- A recent meta-analysis of 24 955 men and 23 339 women demonstrated that the association of the ankle brachial index (ABI) with mortality has a reverse J-shaped distribution in which participants with an ABI of 1.11 to 1.40 are at lowest risk for mortality.<sup>32</sup> Furthermore, an ABI  $<$ 0.90 added meaningfully to the Framingham Risk Score in predicting 10-year risk of total mortality, cardiovascular mortality, and major coronary events. An ABI  $<$ 0.90 approximately doubled the risk of total mortality, cardiovascular mortality, and major coronary events in each Framingham Risk Score category.<sup>32</sup>
- Among 508 patients (449 men) identified from 2 vascular laboratories in San Diego, CA, a decline in ABI of  $>$ 0.15 within a 10-year period was associated with a subsequent increased risk of all-cause mortality (RR 2.4) and CVD mortality (RR of 2.8) at 3 years’ follow-up.<sup>33</sup>
- Among 440 patients with PAD, male sex and smoking were more associated with aortoiliac (proximal) disease than infrailiac (distal) disease. In addition, aortoiliac disease was associated with an increased risk of mortality or cardiovascular events compared with infrailiac disease (adjusted HR 3.28, 95% CI 1.87 to 5.75).<sup>34</sup>
- Men and women with PAD have higher levels of inflammatory biomarkers than individuals without PAD. Elevated levels of C-reactive protein were associated with an increased risk of developing PAD among men in the Physicians’ Health Study.<sup>35</sup> The OR for developing PAD 5 years after C-reactive protein measurement was 2.1 for those in the highest versus lowest baseline quartile of C-reactive protein. Among participants in the Women’s Health Study, 12 years after soluble intercellular adhesion molecule-1 measurement, women in the highest baseline tertile for levels of soluble intercellular adhesion molecule-1 had a 2-fold increased risk of developing PAD compared with women in the lowest baseline tertile.<sup>36</sup> Among individuals with PAD, higher levels of inflammatory biomarkers are associated with increased all-cause and cardiovascular mortality rates and increased risk of failure of lower-extremity revascularization procedures.<sup>37–39</sup>
- Data from the NHANES 1999 to 2004 cohort demonstrated an inverse association between bilirubin levels and prevalence of PAD. A 0.1-mg/dL higher level of bilirubin was associated with a 6% reduction in the odds of PAD (OR 0.94, 95% CI 0.90 to 0.98) after adjustment for PAD risk factors.<sup>40</sup>
- People with PAD have impaired function and quality of life. This is true even for people who do not report leg symptoms. Furthermore, patients with PAD, including those who are asymptomatic, experience a significant decline in lower-extremity functioning over time.<sup>41–43</sup>
- Data from NHANES 1999 to 2000 (NCHS) show that high blood levels of lead and cadmium are associated with an increased prevalence of PAD. Exposure to these 2 metals can occur through cigarette smoke. The risk was 2.8 for high levels of cadmium and 2.9 for high levels of lead. The OR of PAD for current smokers was 4.13 compared with people who had never smoked.<sup>44</sup>
- Results from NHANES 1999 to 2000 (NCHS) and the CHS showed a remarkably high prevalence of PAD among patients with renal insufficiency.<sup>45,46</sup> In addition, chronic kidney disease is common among community-dwelling older men and women with a high ABI.<sup>46</sup>
- Available evidence suggests that the prevalence of PAD in people of Hispanic origin is similar to or slightly higher than that in non-Hispanic whites.<sup>23,47</sup>
- Among patients with established PAD, higher physical activity levels during daily life are associated with better overall survival rate, a lower risk of death because of CVD, and slower rates of functional decline.<sup>48,49</sup> In addition, better 6-minute walk performance and faster walking speed are associated with lower rates of all-cause mortality, cardiovascular mortality, and mobility loss.<sup>50,51</sup>

- A cross-sectional, population-based telephone survey of >2500 adults  $\geq 50$  years of age, with oversampling of blacks and Hispanics, found that 26% expressed familiarity with PAD. Of these, half were not aware that diabetes mellitus and smoking increase the risk of PAD. One in 4 knew that PAD is associated with increased risk of heart attack and stroke, and only 14% were aware that PAD could lead to amputation. All knowledge domains were lower in individuals with lower income and education levels.<sup>52</sup>

### Arrhythmias (Disorders of Heart Rhythm)

ICD-9 426, 427; ICD-10 I46 to I49.

Mortality—40 759. Any-mention mortality—461 872. Hospital discharges—881 000.

- In 2006, \$3.1 billion (\$7783 per discharge) was paid to Medicare beneficiaries for cardiac dysrhythmias.<sup>53</sup>

#### Atrial Fibrillation and Flutter

ICD-9 427.3; ICD-10 I48.

Mortality—14 490. Any-mention mortality—93 594. Prevalence—>2.2 million, projected to 2.66 million in 2010.<sup>54,55</sup> Incidence—>75 000.<sup>55</sup> Hospital discharges—529 000.

- Participants in the NHLBI-sponsored FHS study were followed up from 1968 to 1999. At 40 years of age, remaining lifetime risks for AF were 26.0% for men and 23.0% for women. At 80 years of age, lifetime risks for AF were 22.7% for men and 21.6% for women. In further analysis, counting only those who had development of AF without prior or concurrent HF or MI, lifetime risk for AF was  $\approx 16\%$ .<sup>56</sup>
- Data from a large community-based population suggest that AF is less prevalent in blacks than in whites, both overall and in the setting of congestive heart failure.<sup>54,57</sup>
- Data from the NHDS/NCHS (1996–2001) on cases that included AF as a primary discharge diagnosis found the following<sup>58</sup>:
  - Approximately 44.8% of patients were men.
  - The mean age for men was 66.8 years versus 74.6 years for women.
  - The racial breakdown for admissions was 71.2% white, 5.6% black, and 2.0% other races (20.8% were not specified).
  - Black patients were much younger than patients of other races.
  - The incidence in men ranged from 20.58 per 100 000 people per year for patients between 15 and 44 years of age to 1077.39 per 100 000 people per year for patients  $\geq 85$  years of age. In women, the incidence ranged from 6.64 per 100 000 people per year for patients between 15 and 44 years of age to 1203.7 per 100 000 people per year for those  $\geq 85$  years of age.
  - From 1996 to 2001, hospitalizations with AF as the first-listed diagnosis increased by 34%.
- In 1999, the CDC analyzed data from national and state multiple-cause mortality statistics and Medicare hospital claims for people with AF. The most common disease listed

as the primary diagnosis for people hospitalized with AF was HF (11.8%), followed by AF (10.9%), CHD (9.9%), and stroke (4.9%).<sup>59</sup> In Olmsted County, MN, the age-adjusted incidence of clinically recognized AF in a white population increased by 12.6% between 1980 and 2000.<sup>60,61</sup>

- The incidence of AF was greater in men (incidence ratio for men over women 1.86) and increased markedly with older age.<sup>60</sup>
- If incidence estimates are applied to US population projections from the Census Bureau, the projected number of people with AF may exceed 12 million by 2050.<sup>60</sup>
- Among Medicare patients  $\geq 65$  years of age, AF prevalence increased from 3.2% in 1992 to 6.0% in 2002, with higher prevalence in older subsets of the study population. Stroke rates per 1000 patient-years declined in AF patients on anticoagulants from 46.7 in 1992 to 19.5 in 2002 for ischemic stroke but remained fairly steady for hemorrhagic stroke (1.6 to 2.9).<sup>62</sup>
- AF independently increases the risk of ischemic stroke by 4- to 5-fold.<sup>63</sup>
- AF is responsible for at least 15% to 20% of all ischemic strokes.<sup>55</sup>
- Paroxysmal, persistent, and permanent AF all appear to increase the risk of ischemic stroke to a similar degree.<sup>64</sup>
- AF is also an independent risk factor for ischemic stroke severity and recurrence. In 1 study, people who had AF and were not treated with anticoagulants had a 2.1-fold increase in risk for recurrent stroke and a 2.4-fold increase in risk for recurrent severe stroke.<sup>65</sup>
- Isolated chronic atrial flutter is uncommon but is associated with a high risk of developing AF,<sup>66</sup> and data from a sample of 191 patients with chronic atrial flutter revealed a risk of ischemic stroke that was similar to that for AF.<sup>67</sup>
- A study of >4600 patients diagnosed with first AF showed that risk of death within the first 4 months after the AF diagnosis was high. The most common causes of CVD death were CAD, HF, and ischemic stroke, accounting for 22%, 14%, and 10% respectively, of the early deaths (within the first 4 months) and 15%, 16%, and 7%, respectively, of the late deaths.<sup>61</sup>

#### Other Arrhythmias

##### Tachycardia

ICD-9 427.0, 1, 2; ICD-10 I47.0, I47.1, I47.2, I47.9.

Mortality—601. Any-mention mortality—5921. Hospital discharges—75 000.

##### Paroxysmal Supraventricular Tachycardia

ICD-9 427.0; ICD-10 I47.1.

Mortality—140. Any-mention mortality—1262. Hospital discharges—27 000.

##### Ventricular Fibrillation

ICD-9 427.4; ICD-10 I49.0.

Mortality—1024. Any-mention mortality—9297. Hospital discharges—7000.

VF is listed as the cause of relatively few deaths, but the overwhelming majority of sudden cardiac deaths due to coronary disease (estimated at  $\approx$ 310 000 per year) are thought to be due to ventricular fibrillation.

- In Olmsted County, MN, the incidence of out-of-hospital treated VF decreased from 1985 to 2002<sup>68</sup>:
  - 1985 to 1989: 26.3 per 100 000 (95% CI 21.0 to 32.6)
  - 1990 to 1994: 18.2 per 100 000 (95% CI 14.1 to 23.1)
  - 1995 to 1999: 13.8 per 100 000 (95% CI 10.4 to 17.9)
  - 2000 to 2002: 7.7 per 100 000 (95% CI 4.7 to 11.9)

### Arteries, Diseases of

ICD-9 440 to 448; ICD-10 I70–I79. Includes PAD.

Mortality—30 172. Any-mention mortality—92 168. Hospital discharges—268 000.

#### Aortic Aneurysm

ICD-9 441; ICD-10 I71.

Mortality—12 986. Any-mention mortality—18 346. Hospital discharges—55 000.

- Although the definition varies somewhat by age and body surface area, generally an abdominal aortic aneurysm (AAA) is considered to be present when the anteroposterior diameter of the aorta reaches 3.0 cm.<sup>29</sup>
- The prevalence of AAAs 2.9 to 4.9 cm in diameter ranges from 1.3% in men 45 to 54 years of age to 12.5% in men 75 to 84 years of age. For women, the prevalence ranges from 0% in the youngest to 5.2% in the oldest age groups.<sup>29</sup>
- Factors associated with increased prevalence of AAA include older age, male sex, family history of AAA, tobacco use, hypertension, and manifest atherosclerotic disease in other vascular beds, including the coronary and peripheral arteries.<sup>29,69</sup> The association of dyslipidemia with AAA is mixed.<sup>70</sup>
- Patients with DM are approximately half as likely as patients without DM to have an AAA.<sup>71,72</sup>
- Male sex, older age, and smoking are important risk factors for incident AAA in the next 7 years.<sup>73</sup>
- Large AAAs tend to expand more rapidly than small AAAs, and large AAAs are at substantially higher risk for rupture.<sup>29</sup>
  - Average annual expansion rates are  $\approx$ 1 to 4 mm for aneurysms <4.0 cm in diameter, 4 to 5 mm for AAAs 4.0 to 6.0 cm in diameter, and as much as 7 to 8 mm for AAAs >6.0 cm in diameter.
  - Absolute risk for eventual rupture is  $\approx$ 20% for AAAs >5.0 cm,  $\approx$ 40% for AAAs >6.0 cm, and >50% for AAAs >7.0 cm in diameter.
  - Rupture of an AAA may be associated with death rates as high as 90%.

#### Atherosclerosis

ICD-9 440; ICD-10 I70.

Mortality—8232. Any-mention mortality—46 962. Hospital discharges—123 000.

Atherosclerosis is a process that leads to a group of diseases characterized by a thickening of artery walls. Ath-

erosclerosis causes many deaths due to heart attack and stroke and accounts for nearly three fourths of all deaths because of CVD (FHS, NHLBI).

Analysis of data from the Reduction of Atherothrombosis for Continued Health (REACH) Registry<sup>74</sup> showed that atherothrombosis (CAD, CVD, and PAD) is associated with the main causes of death on a worldwide scale. Despite decreases in age-adjusted death rates, the absolute number of deaths attributable to these conditions continues to increase, and prevalence is increasing sharply in other parts of the world. Atherothrombotic diseases are projected to be the leading cause of death worldwide in 2020. In the REACH study, outpatients with established atherosclerotic arterial disease or at risk of atherothrombosis experienced relatively high annual cardiovascular event rates. Multiple disease locations increased the 1-year risk of cardiovascular events.<sup>75</sup>

#### Other Diseases of Arteries

ICD-9 442 to 448; ICD-10 I72 to I78.

Mortality—8954. Any-mention mortality—30 727. Hospital discharges—90 000.

**Table 10-1. Rheumatic Fever/Rheumatic Heart Disease**

Population Group	Mortality, 2007: All Ages*	Hospital Discharges, 2007: All Ages
Both sexes	3201	61 000
Males	1026 (32.1%)†	22 000
Females	2175 (67.9%)†	39 000
NH white males	907	...
NH white females	1946	...
NH black males	84	...
NH black females	161	...

Ellipses ( . . . ) indicate that data are not available. NH indicates non-Hispanic.

\*Mortality data are for whites and blacks and include Hispanics.

†These percentages represent the portion of total mortality that is for males versus females.

Sources: Mortality: National Center for Health Statistics; data represent underlying cause of death only. Hospital discharges: National Hospital Discharge Survey, National Center for Health Statistics, and National Heart, Lung, and Blood Institute; data include those inpatients discharged alive, dead, or of unknown status.

## 11. Family History and Genetics

### Prevalence

#### Family History of HD

- Among adults  $\geq 20$  years of age, 13.3% reported a parent or sibling with a heart attack or angina before the age of 50 years (NHANES question MCQ300a, combined for 2005 to 2008). The racial/ethnic breakdown is as follows:
  - For non-Hispanic whites, 14.9% for men, 16.7% for women
  - For non-Hispanic blacks, 10.0% for men, 12.4% for women
  - For Mexican Americans, 8.8% for men, 12.3% for women
  - For other races, 11.4% for men, 13.6% for women
- HD occurs as people age, and those without a family history of HD may survive longer, so the prevalence of family history will vary depending on the age at which it is assessed. The breakdown of reported family history of heart attack by age in the US population, as measured by NHANES, is as follows:
  - Age 20 to 39 years, 10.3% for men, 11.6% for women
  - Age 40 to 59 years, 14.1% for men, 18.4% for women
  - Age 60 to 79 years, 12.4% for men, 15.5% for women
  - Age  $\geq 80$  years, 11.2% for men, 9.2% for women
- In the multigenerational FHS, only 75% of participants with a documented parental history of a heart attack before 55 years of age reported that history when asked.<sup>1</sup>

### Impact of Family History

- Premature parental history of a heart attack has been shown to approximately double the risk of a heart attack in men and to increase the risk in women by  $\approx 70\%$ .<sup>2,3</sup>

#### Abbreviations Used in Chapter 11

CVD	cardiovascular disease
FHS	Framingham Heart Study
HD	heart disease
NHANES	National Health and Nutrition Examination Survey
SNP	single nucleotide polymorphism

- Sibling history of a HD has been shown to increase the odds of HD in men and women by  $\approx 50\%$ .<sup>4</sup>

### Genetics

- The increased risk of HD seen in people with a family history of a heart attack is likely due in part to shared genetics. The full genetic basis for CVD has not yet been determined, and genetic markers discovered thus far have not been shown to add to existing cardiovascular risk prediction tools.<sup>5</sup>
- The most consistently replicated genetic marker for HD is located at 9p21.3. At this single nucleotide polymorphism (SNP),  $\approx 27\%$  of the white population is estimated to have 0 risk alleles, 50% is estimated to have 1 risk allele, and the remaining 23% is estimated to have 2 risk alleles.<sup>6</sup>
  - The 10-year HD risk for a 65-year-old man with 2 alleles and no other traditional risk factors is  $\approx 13.2\%$ , whereas a similar man with 0 alleles would have a 10-year risk of  $\approx 9.2\%$ . The 10-year HD risk for a 40-year-old woman with 2 alleles and no other traditional risk factors is  $\approx 2.4\%$ , whereas a similar man with 0 alleles would have a 10-year risk of  $\approx 1.7\%$ .<sup>6</sup>
  - The biological function of the 9p21.3 SNP is not yet known.

## 12. Risk Factor: Smoking/Tobacco Use

See Table 12-1 and Charts 12-1 and 12-2.

### Prevalence

#### Youth

- In 2009, in grades 9 through 12, 19.5% of students reported current cigarette use (on at least 1 day during the 30 days before the survey), 14.0% of students reported current cigar use, and 8.9% of students reported current smokeless tobacco use. Overall, 26.0% of students reported any current tobacco use (YRBSS).<sup>1</sup>
- In 2009, in grades 9 to 12, male and female students were equally likely to report current cigarette use (19.8% compared with 19.1%); however, male students were more likely than female students to report current cigar use (18.6% compared with 8.8%) and current smokeless tobacco use (15.0% compared with 2.2%; YRBSS).<sup>1</sup>
- In 2009, in grades 9 through 12, non-Hispanic white students were more likely than Hispanic or non-Hispanic black students to report any current tobacco use, which includes cigarettes, cigars, or smokeless tobacco (30.3% compared with 20.8% for Hispanic students and 16.2% for non-Hispanic black students; YRBSS).<sup>1</sup>
- Among youths 12 to 17 years of age in 2008, 2.8 million (11.4%) used a tobacco product (cigarettes, cigars, or smokeless tobacco) in the past month, and 2.3 million (9.1%) used cigarettes, a decrease compared with 2007. Cigarette use in the past month in the age group declined from 13.0% in 2002 to 9.1% in 2008 (National Survey on Drug Use and Health [NSDUH]).<sup>2,3</sup>
- Data from the YRBSS<sup>4</sup> for students in grades 9 to 12 indicated the following:
  - The percentage of students who reported ever trying cigarettes remained stable from 1991 to 1999 and then declined from 70.4% in 1999 to 46.3% in 2009.
  - The percentage who reported current cigarette use (on at least 1 day in the 30 days before the survey)

increased between 1991 and 1997 and then declined from 36.4% in 1997 to 19.5% in 2009.

- The percentage who reported current frequent cigarette use (smoked on  $\geq 20$  of the 30 days before the survey) increased from 1991 to 1999 and then declined from 16.8% in 1999 to 7.3% in 2009.

- In 2007, 60.9% of students in grades 9 to 12 who ever smoked cigarettes daily tried to quit smoking cigarettes. The prevalence of this behavior did not vary by grade but was higher among female students (67.3%) than male students (55.5%) and higher among black students (68.1%) than Hispanic students (54.1%). No other differences were found by race/ethnicity. Overall, 12.2% of students who ever smoked cigarettes daily tried to quit smoking cigarettes and were successful (YRBSS).<sup>5</sup>

#### Adults

- From 1998 to 2009, the percentage of US adults  $\geq 18$  years of age who were current cigarette smokers declined from 24.1% to 20.6%; however, the percentage who were current smokers did not change significantly from 2005 to 2009 (NHIS).<sup>6,7</sup>
- In 2009, among Americans  $\geq 18$  years of age, 23.1% of men and 18.1% of women were current cigarette smokers, putting them at increased risk of heart attack and stroke (NHIS).<sup>8</sup>
- From 1998 to 2007, cigarette smoking prevalence among adults  $\geq 18$  years of age decreased in 44 states, the District of Columbia, and Puerto Rico. Six states had no substantial changes in prevalence after controlling for age, sex, and race/ethnicity. However, only Utah and the US Virgin Islands met the Healthy People 2010 target for reducing adult smoking prevalence to 12% (BRFSS).<sup>9</sup>
- In 2009, among adults  $\geq 18$  years of age, the state with the highest percentage of current cigarette smokers was West Virginia (25.5%), and the state with the lowest percentage was Utah (9.8%; BRFSS).<sup>10</sup>
- In 2006 to 2008, Asian adults  $\geq 18$  years of age (men 15.7%, women 4.5%) and Hispanic adults (men 18.4%, women 9.4%) were less likely to be current cigarette smokers than American Indian or Alaska Native adults (men 30.2%, women 22.1%), non-Hispanic white adults (men 24.0%, women 21.0%), and non-Hispanic black adults (men 25.0%, women 17.1%), on the basis of age-adjusted estimates (NHIS).<sup>11</sup>
- In 2004 to 2006 data, adult cigarette smoking varied among Asian subgroups. Most Asian adults had never smoked, with rates ranging from 65% of Korean adults to 84% of Chinese adults. Korean adults (22%) were  $\approx 2$  to 3 times as likely to be current smokers as Japanese (12%), Asian Indian (7%), or Chinese (7%) adults on the basis of age-adjusted estimates (NHIS).<sup>12</sup>
- In 2008, among people  $\geq 65$  years of age, 9.8% of men and 8.5% of women were current smokers. In this age group, men were more likely than women to be former smokers (54.3% compared with 28.9%) on the basis of age-adjusted estimates (NHIS).<sup>13</sup>

### Abbreviations Used in Chapter 12

BRFSS	Behavioral Risk Factor Surveillance System
CDC	Centers for Disease Control and Prevention
CHD	coronary heart disease
CVD	cardiovascular disease
HF	heart failure
MEPS	Medical Expenditure Panel Survey
MI	myocardial infarction
NCHS	National Center for Health Statistics
NHANES	National Health and Nutrition Examination Survey
NHIS	National Health Interview Survey
NHLBI	National Heart, Lung, and Blood Institute
NSDUH	National Survey on Drug Use and Health
SHS	secondhand smoke
YRBSS	Youth Risk Behavior Surveillance System

- Among women 15 to 44 years of age, combined data for 2007 and 2008 indicated that the rate of past-month cigarette use was lower among those who were pregnant (16.4%) than among those who were not pregnant (27.3%). This pattern was evident among women 18 to 25 years of age (22.1% versus 32.3% for pregnant and nonpregnant women, respectively) and among women 26 to 44 years of age (12.6% versus 27.4%, respectively). Among those 15 to 17 years of age, the difference in the rate of cigarette smoking between pregnant and nonpregnant women was not statistically significant (NSDUH).<sup>2</sup>
- In 2008, an estimated 70.9 million Americans  $\geq 12$  years of age were current (past month) users of a tobacco product (cigarettes, cigars, smokeless tobacco, or tobacco in pipes). The rate of current use of any tobacco product in this age range remained steady from 2007 to 2008 (28.6% and 28.4%, respectively; NSDUH).<sup>2</sup>

### Incidence

- In 2008,  $\approx 2.4$  million people  $\geq 12$  years of age smoked cigarettes for the first time within the past 12 months, which was similar to the estimate in 2007 (2.2 million). The 2008 estimate averages out to  $\approx 6600$  new cigarette smokers every day. Most new smokers (58.8%) in 2008 were  $< 18$  years of age when they first smoked cigarettes (NSDUH).<sup>2</sup>
- Data from 2002 to 2004 suggest that  $\approx 1$  in 5 nonsmokers 12 to 17 years of age is likely to start smoking. Youths in the Mexican subpopulations were significantly more susceptible (28.8%) to start smoking than those in non-Hispanic white (20.8%), non-Hispanic black (23.0%), Cuban (16.4%), Asian Indian (15.4%), Chinese (15.3%), and Vietnamese (13.8%) subpopulations. There was no significant difference in susceptibility to start smoking between boys and girls in any of the major populations or subpopulations (NSDUH).<sup>14</sup>
- Approximately 80% of people who use tobacco began at  $< 18$  years of age, according to a report from the Surgeon General of the United States. The most common age of initiation is 14 to 15 years.<sup>15</sup>

### Mortality

- During 2000 to 2004, cigarette smoking resulted in an estimated 443 000 premature deaths each year due to smoking-related illnesses, and  $\approx 49$  000 of these deaths were due to secondhand smoke (SHS). In adults  $\geq 35$  years of age, a total of 32.7% of these deaths were related to CVD.<sup>16</sup>
- Each year from 2000 to 2004, smoking caused 3.1 million years of potential life lost for males and 2.0 million years for females, excluding deaths due to smoking-attributable residential fires and adult deaths due to SHS.<sup>16</sup>
- From 2000 to 2004, smoking during pregnancy resulted in an estimated 776 infant deaths annually.<sup>16</sup>
- During 2000 to 2004, cigarette smoking resulted in an estimated 269 655 deaths annually among males and 173 940 deaths annually among females.<sup>16</sup>

- On average, male smokers die 13.2 years earlier than male nonsmokers, and female smokers die 14.5 years earlier than female nonsmokers.<sup>17</sup>
- Current cigarette smoking is a powerful independent predictor of cardiac arrest in patients with CHD.<sup>18</sup>
- After up to 14.5 years of follow-up of participants in the Lung Health Study of the NHLBI, the all-cause death rate among participants in a smoking-cessation intervention was significantly lower (15%) than among those given usual care.<sup>19</sup>

### Secondhand Smoke

- The national prevalence of households with smoke-free home rules increased from 43.2% during 1992 to 1993 to 72.2% in 2003 on the basis of data from the "Tobacco Use Supplement" to the "Current Population Survey." During this period, the prevalence of such rules increased from 9.6% to 31.8% among households with at least 1 smoker and from 56.8% to 83.5% among households with no smokers. Approximately 126 million children and non-smoking adults were still exposed to SHS in the United States as of 1999 to 2002.<sup>20</sup>
- In 2008, data from 11 states showed that the majority of people surveyed in each state reported having smoke-free home rules, ranging from 68.8% in West Virginia to 85.6% in Arizona (BRFSS).<sup>21</sup>
- The percentage of the US nonsmoking population with detectable serum cotinine declined from 52.5% in 1999 to 2000 to 40.1% in 2007 to 2008, with declines occurring for children and adults. During 2007 to 2008, the percentage of nonsmokers with detectable serum cotinine was higher for those 3 to 11 years of age (53.6%) and those 12 to 19 years of age (46.5%) than for those  $\geq 20$  years of age (36.7%); the percentage was also higher for non-Hispanic blacks (55.9%) than for non-Hispanic whites (40.1%) and Mexican Americans (28.5%; NHANES).<sup>22</sup>
- Data from a 2006 report of the US Surgeon General on the consequences of involuntary exposure to tobacco smoke<sup>23</sup> indicate the following:
  - Nonsmokers who are exposed to SHS at home or at work increase their risk of developing CHD by 25% to 30%.
  - Short exposures to SHS can cause blood platelets to become stickier, damage the lining of blood vessels, and decrease coronary flow velocity reserves, potentially increasing the risk of an acute MI.

### Aftermath

- Among ever-smokers who had 1 circulatory disorder, 52.1% were current smokers, and among those who reported that they had  $\geq 3$  circulatory disorders, 28% were current smokers at the time of the interview. The adjusted odds of being a current smoker were lower for individuals who had  $\geq 2$  central circulatory disorders, such as MI, HF, or stroke, than for those without a central circulatory disorder.<sup>24</sup>

- The CDC's "Health Effects of Cigarette Smoking" fact sheet<sup>25</sup> provides the following information:
  - Cigarette smokers are 2 to 4 times more likely to develop CHD than nonsmokers.
  - Cigarette smoking approximately doubles a person's risk for stroke.
  - Cigarette smokers are >10 times as likely as nonsmokers to develop peripheral vascular disease.
  - Smoking increases the risk of abdominal aortic aneurysm.
- In 2006, 62.9% of adult current smokers 18 to 64 years of age with a checkup during the preceding year reported that they had been advised to quit, about the same percentage as in 2002 (63.5%; MEPS).<sup>26</sup>

## Cost

Direct medical costs (\$96 billion) and lost productivity costs (\$97 billion) associated with smoking totaled an estimated \$193 billion per year between 2000 and 2004.<sup>16</sup>

**Table 12-1. Cigarette Smoking**

Population Group	Prevalence, 2009	
	Age ≥18 y*	Cost <sup>15</sup>
Both sexes	46 600 000 (20.6%)	\$193 billion per year
Men	25 700 000 (23.1%)	...
Women	21 100 000 (18.1%)	...
NH white men	25.0%	...
NH white women	20.7%	...
NH black men	22.9%	...
NH black women	18.8%	...
Hispanic or Latino men	17.6%	...
Hispanic or Latino women	9.4%	...
Asian only (both sexes)	11.6%	...
American Indian/Alaska Native only (both sexes)	19.0%	...

Ellipses ( . . . ) indicate data not available; NH indicates non-Hispanic. Percentages are age-adjusted. Estimates for Asian only, and American/Alaska Native only include non-Hispanic and Hispanic persons. \*Data derived from Centers for Disease Control and Prevention/National Center for Health Statistics/National Health Interview Survey.<sup>7</sup>

**Chart 12-1.** Prevalence (%) of students in grades 9 to 12 reporting current cigarette use by sex and race/ethnicity (Youth Risk Behavior Surveillance System, 2009). NH indicates non-Hispanic. Data derived from *MMWR: Morbidity and Mortality Weekly Report*.<sup>1</sup>

**Chart 12-2.** Prevalence (%) of current smoking for adults >18 years of age by race/ethnicity and sex (National Health Interview Survey: 2006–2008). All percentages are age-adjusted. NH indicates non-Hispanic. \*Includes both Hispanics and non-Hispanics. Data derived from Centers for Disease Control and Prevention/National Center for Health Statistics, Health Data Interactive.<sup>11</sup>

### 13. Risk Factor: High Blood Cholesterol and Other Lipids

See Table 13-1 and Charts 13-1 through 13-3.

#### Prevalence

For information on dietary cholesterol, total fat, saturated fat, and other factors that affect blood cholesterol levels, see Chapter 19 (Nutrition).

#### Youth

- Among children 4 to 11 years of age, the mean total blood cholesterol level is 164.5 mg/dL. For boys, it is 163.8 mg/dL; for girls, it is 165.2 mg/dL. The racial/ethnic breakdown is as follows (NHANES 2005–2008, NCHS and NHLBI; unpublished analysis):
  - For non-Hispanic whites, 163.9 mg/dL for boys and 165.6 mg/dL for girls
  - For non-Hispanic blacks, 165.7 mg/dL for boys and 162.3 mg/dL for girls
  - For Mexican Americans, 160.7 mg/dL for boys and 161.5 mg/dL for girls
- Among adolescents 12 to 19 years of age, the mean total blood cholesterol level is 159.2 mg/dL. For boys, it is 156.3 mg/dL; for girls, it is 162.3 mg/dL. The racial/ethnic breakdown is as follows (NHANES 2005–2008, NCHS and NHLBI; unpublished analysis):
  - For non-Hispanic whites, 155.9 mg/dL for boys and 162.3 mg/dL for girls
  - For non-Hispanic blacks, 157.7 mg/dL for boys and 163.6 mg/dL for girls
  - For Mexican Americans, 156.9 mg/dL for boys and 161.3 mg/dL for girls
- The prevalence of abnormal lipid levels among youths 12 to 19 years of age is 20.3%; 14.2% of normal-weight youths, 22.3% of overweight youths, and 42.9% of obese youths have at least 1 abnormal lipid level (NHANES 1999–2006, NCHS).<sup>1</sup>
- Approximately 8.5% of adolescents 12 to 19 years of age have total cholesterol levels  $\geq 200$  mg/dL (NHANES 2005–2008, NCHS and NHLBI; unpublished analysis).

#### Abbreviations Used in Chapter 13

BRFSS	Behavioral Risk Factor Surveillance System
CDC	Centers for Disease Control and Prevention
CHD	coronary heart disease
HD	heart disease
HDL	high-density lipoprotein
LDL	low-density lipoprotein
mg/dL	milligrams per deciliter
mmol/L	millimoles per liter
NCHS	National Center for Health Statistics
NHANES	National Health and Nutrition Examination Survey
NHLBI	National Heart, Lung, and Blood Institute

- Fewer than 1% of adolescents are eligible for pharmacological treatment.<sup>1,2</sup>

#### Adults

- An estimated 33 500 000 adults  $\geq 20$  years of age have total serum cholesterol levels  $\geq 240$  mg/dL (extrapolated to 2008 by use of NCHS/NHANES 2005–2008 data), with a prevalence of 16.2% (Table 13-1; NCHS and NHLBI, unpublished analysis).
- Data from NHANES 1999–2006 showed that  $\approx 8\%$  of adults  $\geq 20$  years of age have undiagnosed hypercholesterolemia.<sup>3</sup>
- Data from the BRFSS study of the CDC in 2009 showed that the percentage of adults who had been screened for high blood cholesterol in the preceding 5 years ranged from 67.5% in Utah to 85.3% in the District of Columbia. The median percentage among all 50 states was 77.0%.<sup>4</sup>
- The percentage of adults who reported having had a cholesterol check increased from 68.6% during 1999–2000 to 74.8% during 2005–2006.<sup>5</sup>
- A 10% (population-wide) decrease in total cholesterol levels may result in an estimated 30% reduction in the incidence of CHD.<sup>6</sup>
- Data from NHANES 1999–2002 (NCHS) showed that overall, 63.3% of participants whose test results indicated high blood cholesterol or who were taking a cholesterol-lowering medication had been told by a professional that they had high cholesterol. Women were less likely than men to be aware of their condition; blacks and Mexican Americans were less likely to be aware of their condition than were whites. Fewer than half of Mexican Americans with high cholesterol were aware of their condition.<sup>7</sup>
- Between the periods 1988–1994 and 1999–2002 (NHANES/NCHS), the age-adjusted mean total serum cholesterol level of adults  $\geq 20$  years of age decreased from 206 to 203 mg/dL, and LDL cholesterol levels decreased from 129 to 123 mg/dL.<sup>8</sup>
- Data from NHANES 2003–2006 (NCHS) showed the serum total crude mean cholesterol level in adults  $\geq 20$  years of age was 198 mg/dL for men and 202 mg/dL for women.<sup>9</sup>
- Data from the Minnesota Heart Survey (1980–1982 to 2000–2002) showed a decline in age-adjusted mean total cholesterol concentrations from 5.49 and 5.38 mmol/L for men and women, respectively, in 1980–1982 to 5.16 and 5.09 mmol/L, respectively, in 2000–2002; however, the decline was not uniform across all age groups. Middle-aged to older people have shown substantial decreases, but younger people have shown little overall change and recently had increased total cholesterol values. Lipid-lowering drug use rose significantly for both sexes among those 35 to 74 years of age. Awareness, treatment, and control of hypercholesterolemia have increased; however, more than half of those at borderline-high risk remain unaware of their condition.<sup>10</sup>
- Data from the BRFSS (CDC) survey in 2009 showed that among adults screened for high blood cholesterol, the percentage who had been told that they had high blood cholesterol ranged from 32.9% in Tennessee to 41.8% in South Carolina. The median percentage among states was 37.5%.<sup>4</sup>
- Among adults with hypercholesterolemia, the percentage who had been told that they had high cholesterol increased from 42.0% during 1999–2000 to 50.4% during 2005–2006.<sup>5</sup>
- According to data from NHANES 2005–2006, between the periods 1999–2000 and 2005–2006, mean serum total cho-

lesterol levels in adults  $\geq 20$  years of age declined from 204 to 199 mg/dL. This decline was observed for men  $\geq 40$  years of age and for women  $\geq 60$  years of age. There was little change over this time period for other sex/age groups. In 2005–2006,  $\approx 65\%$  of men and 70% of women had been screened for high cholesterol in the past 5 years, and 16% of adults had serum total cholesterol levels of 240 mg/dL or higher.<sup>11</sup>

- Self-reported use of cholesterol-lowering medications increased from 8.2% during 1999–2000 to 14.0% during 2005–2006.<sup>5</sup>
- According to data from NHANES, from 1999 to 2006, the prevalence of elevated LDL cholesterol levels in adults  $> 20$  years of age has decreased by  $\approx 33\%$ .<sup>12</sup>

## Adherence

### Youth

Analysis of data from NHANES 1999–2006 showed that the overall prevalence of abnormal lipid levels among youths 12 to 19 years of age was 20.3%.<sup>1</sup>

### Adults

- On the basis of data from the Third Report of the Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults<sup>13</sup>:
  - Fewer than half of all people who qualify for any kind of lipid-modifying treatment for CHD risk reduction are receiving it.
  - Fewer than half of even the highest-risk people (those with symptomatic CHD) are receiving lipid-lowering treatment.
  - Only about one third of treated patients are achieving their LDL goal;  $< 20\%$  of patients with CHD are at their LDL goal.
- Data from NHANES 2005–2006 indicate that among those with elevated LDL cholesterol levels, 35.5% had not been screened previously, 24.9% were screened but not told they had elevated cholesterol, and 39.6% were treated inadequately.<sup>12</sup>

## Lipid Levels

### LDL (Bad) Cholesterol

#### Youth

- Among adolescents 12 to 19 years of age, the mean LDL cholesterol level is 88.5 mg/dL. For boys, it is 87.1 mg/dL, and for girls, it is 89.9 mg/dL. The racial/ethnic breakdown is as follows (NHANES 2005–2008, NCHS and NHLBI; unpublished analysis):
  - Among non-Hispanic whites, 87.6 mg/dL for boys and 89.8 mg/dL for girls
  - Among non-Hispanic blacks, 88.8 mg/dL for boys and 92.6 mg/dL for girls
  - Among Mexican Americans, 88.4 mg/dL for boys and 88.8 mg/dL for girls
- High levels of LDL cholesterol occurred in 8.4% of male adolescents and 6.8% of female adolescents during 1999–2006.<sup>1</sup>

#### Adults

- The mean level of LDL cholesterol for American adults  $\geq 20$  years of age was 115.2 mg/dL in 2008.<sup>12</sup> Levels of 130 to 159 mg/dL are considered borderline high, levels of 160 to 189 mg/dL are classified as high, and levels of  $\geq 190$  mg/dL are considered very high.
- According to NHANES 2005–2008 (NCHS and NHLBI; unpublished data):
  - Among non-Hispanic whites, mean LDL cholesterol levels were 114.5 mg/dL for men and 115.8 mg/dL for women.
  - Among non-Hispanic blacks, mean LDL cholesterol levels were 114.6 mg/dL for men and 111.5 mg/dL for women.
  - Among Mexican Americans, mean LDL cholesterol levels were 121.2 mg/dL for men and 113.6 mg/dL for women.
- The age-adjusted prevalence of high LDL cholesterol in US adults was 26.6% in 1988–1994 and 25.3% in 1999–2004 (NHANES/NCHS). Between 1988–1994 and 1999–2004, awareness increased from 39.2% to 63.0%, and use of pharmacological lipid-lowering treatment increased from 11.7% to 40.8%. LDL cholesterol control increased from 4.0% to 25.1% among those with high LDL cholesterol. In 1999–2004, rates of LDL cholesterol control were lower among adults 20 to 49 years of age than among those  $\geq 65$  years of age (13.9% versus 30.3%, respectively), among non-Hispanic blacks and Mexican Americans than among non-Hispanic whites (17.2% and 16.5% versus 26.9%, respectively), and among men than among women (22.6% versus 26.9%, respectively).<sup>14</sup>
- Mean levels of LDL cholesterol decreased from 126.1 mg/dL during 1999–2000 to 114.8 mg/dL during 2005–2006. The prevalence of high LDL cholesterol decreased from 31.5% during 1999–2000 to 21.2% during 2005–2006.<sup>12</sup>

### HDL (Good) Cholesterol

#### Youth

- Among children 4 to 11 years of age, the mean HDL cholesterol level is 54.7 mg/dL. For boys, it is 55.6 mg/dL, and for girls, it is 53.6 mg/dL. The racial/ethnic breakdown is as follows (NHANES 2005–2008, NCHS and NHLBI; unpublished analysis):
  - Among non-Hispanic whites, 54.7 mg/dL for boys and 52.8 mg/dL for girls
  - Among non-Hispanic blacks, 61.4 mg/dL for boys and 58.1 mg/dL for girls
  - Among Mexican Americans, 53.6 mg/dL for boys and 51.1 mg/dL for girls
- Among adolescents 12 to 19 years of age, the mean HDL cholesterol level is 51.6 mg/dL. For boys, it is 49.3 mg/dL, and for girls, it is 54.0 mg/dL. The racial/ethnic breakdown is as follows (NHANES 2005–2008, NCHS and NHLBI; unpublished analysis):
  - Among non-Hispanic whites, 48.1 mg/dL for boys and 53.3 mg/dL for girls

- Among non-Hispanic blacks, 54.6 mg/dL for boys and 56.9 mg/dL for girls
- Among Mexican Americans, 48.3 mg/dL for boys and 53.5 mg/dL for girls
- Low levels of HDL cholesterol occurred in 11% of male adolescents and 4% of female adolescents during 1999–2006.<sup>1</sup>

*Adults*

- An HDL cholesterol level below 40 mg/dL in adults is considered low and is a risk factor for HD and stroke. The mean level of HDL cholesterol for American adults  $\geq 20$  years of age is 53.3 mg/dL (NHANES 2005–2008, NCHS and NHLBI; unpublished analysis).
- According to NHANES 2005–2008 (NCHS and NHLBI; unpublished analysis):
  - Among non-Hispanic whites, mean HDL cholesterol levels were 47.2 mg/dL for men and 58.8 mg/dL for women.
  - Among non-Hispanic blacks, mean HDL cholesterol levels were 52.3 mg/dL for men and 61.3 mg/dL for women.
  - Among Mexican Americans, mean HDL cholesterol levels were 46.0 mg/dL for men and 54.2 mg/dL for women.

*Triglycerides*

*Youth*

- Among adolescents 12 to 19 years of age, the mean triglyceride level is 87.8 mg/dL. For boys, it is 87.2 mg/dL, and for girls, it is 88.5 mg/dL. The racial/ethnic breakdown is as follows (NHANES 2005–2008, NCHS and NHLBI; unpublished analysis):
  - Among non-Hispanic whites, 92.7 mg/dL for boys and 90.9 mg/dL for girls
  - Among non-Hispanic blacks, 68.8 mg/dL for boys and 63.0 mg/dL for girls
  - Among Mexican Americans, 94.5 mg/dL for boys and 90.2 mg/dL for girls
- High levels of triglycerides occurred in 11.4% of male adolescents and 8.8% of female adolescents during 1999–2006.<sup>1</sup>

*Adults*

- A triglyceride level  $>150$  mg/dL in adults is considered elevated and is a risk factor for HD and stroke. The mean level of triglycerides for American adults  $\geq 20$  years of age is 137.6 mg/dL (NHANES 2005–2008, NCHS and NHLBI; unpublished analysis).
  - Among men, the mean triglyceride level is 149.9 mg/dL (NHANES 2005–2008, NCHS and NHLBI; unpublished analysis). The racial/ethnic breakdown is as follows:
    - 150.2 mg/dL for white men
    - 120.1 mg/dL for black men
    - 169.4 mg/dL for Mexican American men

- Among women, the mean triglyceride level is 125.5 mg/dL, with the following racial/ethnic breakdown:
  - 128.8 mg/dL for white women
  - 97.0 mg/dL for black women
  - 139.0 mg/dL for Mexican American women

- Approximately 33% of adults  $\geq 20$  years of age had a triglyceride level  $\geq 150$  mg/dL during 1999–2004.<sup>15</sup>
- Fewer than 3% of adults with a triglyceride level  $\geq 150$  mg/dL received pharmacological treatment during 1999–2004.<sup>15</sup>

LDL indicates low-density lipoprotein; HDL, high-density lipoprotein; and NH, non-Hispanic.

Prevalence of total cholesterol  $\geq 200$  mg/dL includes people with total cholesterol  $\geq 240$  mg/dL. In adults, levels of 200 to 239 mg/dL are considered borderline high. Levels of  $\geq 240$  mg/dL are considered high.

\*Total data for total cholesterol are for Americans  $\geq 20$  years of age. Data for LDL cholesterol, HDL cholesterol, and all racial/ethnic groups are age adjusted for age  $\geq 20$  years.

Source for total cholesterol  $\geq 200$  mg/dL,  $\geq 240$  mg/dL, LDL, and HDL: National Health and Nutrition Examination Survey (2005–2008), National Center for Health Statistics, and National Heart, Lung, and Blood Institute. Estimates from National Health and Nutrition Examination Survey 2005–2008 (National Center for Health Statistics) applied to 2008 population estimates.

**Chart 13-1.** Trends in mean total serum cholesterol among adolescents 12 to 17 years of age by race, sex, and survey year (National Health and Nutrition Examination Survey: 1988–1994,\* 1999–2004, and 2005–2008). Values are in mg/dL. NH indicates non-Hispanic; Mex. Am., Mexican American. \*Data for Mexican Americans not available. Source: National Center for Health Statistics and National Heart, Lung, and Blood Institute.

**Chart 13-2.** Trends in mean total serum cholesterol among adults ages  $\geq 20$  years old by race and survey year (National Health and Nutrition Examination Survey: 1988–1994, 1999–2004, and 2005–2008). Values are in mg/dL. NH indicates non-Hispanic. Source: National Center for Health Statistics and National Heart, Lung, and Blood Institute.

**Chart 13-3.** Age-adjusted trends in the prevalence of total serum cholesterol  $\geq 200$  mg/dL in adults  $\geq 20$  years of age by sex, race/ethnicity, and survey year (National Health and Nutrition Examination Survey 2003–2004, 2005–2006, and 2007–2008). NH indicates non-Hispanic; Mex. Am., Mexican American.

## 14. Risk Factor: Physical Inactivity

See Table 14-1 and Charts 14-1 through 14-4.

### Prevalence

#### Youth

##### Inactivity

- The proportion of adolescents (12 to 19 years old) who report engaging in no regular PA is high and varies by sex and race.<sup>1</sup>
- Nationwide, 23.1% of adolescents were inactive during the previous 7 days, indicated by their response that they did not participate in  $\geq 60$  minutes of any kind of PA that increased their heart rate and made them breathe hard on any 1 of the previous 7 days.<sup>1</sup>
- Girls were more likely than boys to report inactivity (29.9% versus 17.0%).<sup>1</sup>
- The prevalence of inactivity was highest in black (43.6%) and Hispanic (30.5%) girls, followed by white girls (25.4%), black boys (20.6%), Hispanic boys (17.4%), and white boys (15.9%; CDC).<sup>1</sup>
- Nationwide, 24.9% of adolescents used a computer for activities other than school work (eg, videogames or other computer games) for  $\geq 3$  hours per day on an average school day.<sup>1</sup>
- A greater proportion of black and Hispanic students used computers or watched television  $> 3$  hours per day than white students.<sup>2</sup>

### Abbreviations Used in Chapter 14

BP	blood pressure
CDC	Centers for Disease Control and Prevention
CHD	coronary heart disease
CI	confidence interval
CVD	cardiovascular disease
DBP	diastolic blood pressure
DM	diabetes mellitus
EF	ejection fraction
HDL	high-density lipoprotein
HF	heart failure
HR	hazard ratio
LDL	low-density lipoprotein
MEPS	Medical Expenditure Panel Survey
MET	metabolic equivalent tasks
MI	myocardial infarction
MVPA	moderate-to-vigorous physical activity
NCHS	National Center for Health Statistics
NHANES	National Health and Nutrition Examination Survey
NHIS	National Health Interview Survey
PA	physical activity
PAD	peripheral arterial disease
RR	relative risk
WHO	World Health Organization

### Activity Recommendations

- The proportion of students who met activity recommendations declined from 9th (39.7%) to 12th (31.6%) grades, and at each grade level, the proportion was higher in boys than in girls.<sup>1</sup>
- More adolescent boys (45.6%) than girls (27.7%) self-reported having been physically active at least 60 minutes per day on 5 or more days; self-reported rates of activity were higher in white (39.9%) than in black (32.6%) or Hispanic (33.1%) adolescents.<sup>1</sup>
- There was a marked discrepancy between the proportion of youth (ages 6 to 11 years) who reported engaging in  $\geq 60$  minutes of moderate-to-vigorous physical activity (MVPA) on most days of the week and those who actually engaged in MVPA for  $\geq 60$  minutes when activity was measured objectively with accelerometers (ie, portable motion sensors that record and quantify the duration and intensity of movements) in the NHANES 2003–2004 survey.<sup>3</sup>
- On the basis of accelerometer counts per minute  $> 2020$ , 42% of 6- to 11-year-olds accumulated  $\geq 60$  minutes of MVPA on 5 of 7 days per week, whereas only 8% of 12- to 15-year-olds and 7.6% of 16- to 19-year-olds achieved similar counts.<sup>3</sup>
- More boys than girls met PA recommendations ( $\geq 60$  minutes of moderate to vigorous activity on most days of the week) as measured by accelerometry.<sup>3</sup>
- Fewer than 50% of adolescents (14 to 17 years of age) met PA guideline recommendations; 57% of boys met recommendations versus 40% of girls.<sup>4</sup>

### Structured Activity Participation

- Despite recommendations from the National Association for Sport and Physical Education that schools should require daily physical education for students in kindergarten through 12th grade, only 33.3% of students attended physical education classes in school daily (34.6% of boys and 31.9% of girls).<sup>1,5</sup>
- Physical education class participation declined from the 9th through the 12th grades among boys and girls.<sup>2</sup>
- Among children 9 to 13 years old, 61.5% do not participate in any organized PA during nonschool hours and 22.6% do not engage in any free-time PA, according to 2002 data from the Youth Media Campaign Longitudinal Study of the CDC.<sup>6</sup>
- Little more than half (58.3%) of all students played on at least 1 school or community sports team in the previous year; however, the prevalence declined with increasing grade level, from 61.6% in the 9th grade to 51.1% in the 12th grade.<sup>1</sup>

### Adults

#### Inactivity

- Thirty-three percent of adults ( $> 18$  years of age) do not engage in leisure-time PA according to 2009 data from the NHIS (“no leisure-time physical activity/inactivity” refers to no sessions of light/moderate or vigorous PA of at least 10 minutes’ duration).<sup>7</sup>

- Inactivity in 2009 was higher among women than men (34.5% versus 30.3%, age adjusted) and increased with age from 27.7% to 33.3%, 38.2%, and 55.3% among adults 18 to 44, 45 to 64, 65 to 74, and  $\geq 75$  years of age, respectively.<sup>7</sup>
- Non-Hispanic black and Hispanic adults were more likely to report inactivity (0.8.7% and 44.0%, respectively) than were non-Hispanic white adults (28.4%), based on age-adjusted estimates from the 2009 NHIS.<sup>7</sup>
- Fifty-six percent of adults who responded to the 2009 NHIS survey reported engaging in no vigorous activity (activity that causes heavy sweating and a large increase in breathing or heart rate).<sup>7</sup>
- Women (60.1%) were more likely than men (50.3%) to report never engaging in vigorous PA, based on age-adjusted estimates from the 2009 NHIS.<sup>7</sup>
- The proportion of respondents who did not participate in any vigorous activity increased with age from 45.7% in 18- to 44-year-olds to 86.8% in adults  $\geq 75$  years of age in the 2009 NHIS.<sup>7</sup>
- American Indians/Alaska Natives (61.7%), blacks (61.6%), and Asians (61.4%) were more likely to report not engaging in any vigorous activity than whites (54.1%), and Hispanic/Latino adults were more likely not to engage in any vigorous activity (66.9%) than non-Hispanic/non-Latino adults (53.3%) according to age-adjusted estimates from the 2009 NHIS.<sup>7</sup>
- The probability of not engaging in any vigorous activity was inversely associated with education; participants with no high school diploma (77.6%), a high school diploma (66.2%), some college (54.0%), or bachelor's degree or higher (39.3%), respectively, reported that they did not engage in any vigorous PA, based on the 2009 NHIS.<sup>7</sup>

#### Activity Recommendations

- The proportion of adults reporting levels of PA consistent with the Healthy People 2010 objectives remains low and decreases with age.<sup>8</sup>
- Thirty-three percent of respondents in a study examining awareness of current US PA guidelines had direct knowledge of the recommended dosage of PA (ie, frequency/duration).<sup>9</sup>
- The age-adjusted proportion of adults 18 years and older who reported engaging in regular moderate or vigorous PA as defined by the Healthy People 2010 objective 22-2 was 32%, based on the 2008 NHIS (CDC, Data2010; available at <http://wonder.cdc.gov/data2010/>).
- The percentage of adults reporting regular moderate or vigorous PA decreased with age from 38% for adults 18 to 24 years of age to 18% for those  $\geq 75$  years, based on the 2008 NHIS (CDC, Data2010; available at <http://wonder.cdc.gov/data2010/>).
- In 2008, 27% of adults participated in leisure-time strengthening activities, an important component of overall physical fitness.
  - The percentage of men who engaged in leisure-time strengthening activities decreased with age, from 47% at age 18 to 24 years to 16% at age  $\geq 75$  years. The percentage of women who engaged in leisure-time

strengthening activities also decreased with age, from 28% at age 18 to 24 years to 11% at age  $\geq 75$  years.<sup>10</sup>

- The proportion of adults reporting regular leisure-time activity (30 minutes of light or moderate activity  $\geq 5$  times per week or 20 minutes of vigorous activity  $\geq 3$  times per week) in the 2009 NHIS was positively associated with education level: 46.0% of people with a college degree or higher were regularly active compared with 21.4% of adults with less than a high school diploma.<sup>7</sup>
- Adherence to PA recommendations was much lower when based on PA measured by accelerometer in NHANES 2003–2004<sup>3</sup>:
  - Among adults 20 to 59 years of age, 3.8% of men and 3.2% of women met recommendations to engage in MVPA (accelerometer counts  $>2020/\text{min}$ ) for 30 minutes (in sessions of  $\geq 10$  minutes) on  $\geq 5$  of 7 days.
  - Among people  $\geq 60$  years of age, adherence was 2.5% in men and 2.3% in women.
- In a review examining self-reported versus actual measured PA (eg, accelerometers, pedometers, indirect calorimetry, double-labeled water, heart rate monitor), 60% of respondents self-reported higher values of activity than what was measured by use of direct methods.
  - Among men, self-reported PA was 44% greater than actual measured values; among women, self-reported activity was 138% greater than actual measured PA.<sup>11</sup>

## Trends

### Youth

- A study of 3068 youths between the ages of 14 and 24 years from 1999 to 2006 found that the prevalence of inactivity went up with age in both boys and girls.
  - Across ages, girls had a higher prevalence of physical inactivity than boys.<sup>12</sup>
  - In a study of 12 812 youth ages 9 to 18 years, the PA level in boys and girls declines starting at the age of 13, with a significantly greater decline in activity among girls.<sup>13</sup>

### Adults

- Between NHANES III (1988–1994) and NHANES 2001–2006, the proportion of adults who engaged in  $>12$  bouts of PA per month declined from 57% to 43% in men and from 49% to 43% in women.
- In non-Hispanic whites, the activity level has decreased from 55.3% to 45.2%; for non-Hispanic blacks, it has decreased from 41.2% to 34.6%; and for Hispanics, the decline has been from 40.9% to 36.2%.<sup>14</sup>

## CHD Risk Factors

### Youth

- More girls (67.9%) than boys (55.7%) reported having exercised to lose weight or to keep from gaining weight.

- White girls (72.2%) were more likely than black (54.2%) and Hispanic (66.3%) girls to report exercising to lose weight or to keep from gaining weight.<sup>1</sup>
- Total and vigorous PA are inversely correlated with body fat and the prevalence of obesity.<sup>15</sup>
- Physical inactivity was positively correlated with CHD risk factors (eg, mean arterial pressure, triglycerides, LDL, HDL, and fasting plasma glucose) in youths. Findings were similar for boys and girls.<sup>16</sup>

### Adults

- Participants in the Diabetes Prevention Project randomized trial who met the PA goal of 150 minutes of PA per week were 44% less likely to develop DM, even if they did not meet the weight-loss target.<sup>17</sup>
- As a weight-loss intervention, exercise alone was associated with significant reductions in DBP (−2 mm Hg, 95% CI −4 to −1 mm Hg), triglycerides (−0.2 mmol/L, 95% CI −0.3 to −0.1 mmol/L), and fasting glucose (−0.2 mmol/L, 95% CI −0.3 to −0.1 mmol/L).<sup>18</sup>
- A total of 120 to 150 minutes per week of moderate-intensity activity can reduce the risk of developing metabolic syndrome and its individual components (ie, abdominal adiposity, high BP, low HDL cholesterol, high triglycerides, or high glucose).<sup>19</sup>

### CHD Events and Mortality

- The PA guidelines for adults cite evidence that ≈150 minutes a week of moderate-intensity aerobic activity can reduce the risk of CVD.<sup>20</sup>
  - The RR of CHD associated with physical inactivity ranges from 1.5 to 2.4.<sup>21</sup>
  - Physical inactivity is responsible for 12.2% of the global burden of MI after accounting for other CVD risk factors such as cigarette smoking, DM, hypertension, abdominal obesity, lipid profile, no alcohol intake, and psychosocial factors.<sup>22</sup>
  - A 2.3% decline in physical inactivity between 1980 and 2000 prevented or postponed ≈17 445 deaths (≈5%) due to CHD in the United States.<sup>23</sup>
  - The Nurse's Health Study of >72 000 female nurses indicated that moderate-intensity PA, such as walking, is associated with a substantial reduction in risk of total and ischemic stroke.<sup>24</sup>
- Longitudinal studies commonly report a graded, inverse association of PA amount and duration (ie, dose) with incident CHD and stroke.<sup>25</sup>
  - In the Health Professionals Follow-Up Study, PA “dose” was inversely associated with the incidence of CHD over time, with rates declining from 46.3, 39.3, 35.9, 32.2, and 25.8 cases per 10 000 person years according to quintiles of activity. The adjusted HR comparing the uppermost quintile of activity with the lowest was 0.72 (95% CI 0.61 to 0.85).<sup>26</sup>
  - Metabolic equivalent tasks (MET) levels >6 were associated with a statistically significantly lower RR (RR 0.83,

95% CI 0.74 to 0.97 versus MET intensity of 1 to 3.9) of developing incident CHD in the Health Professionals Follow-Up Study of men.<sup>26</sup>

- In a meta-analysis of longitudinal studies among women, RRs of incident CHD were 0.83 (95% CI 0.69 to 0.99), 0.77 (95% CI 0.64 to 0.92), 0.72 (95% CI 0.59 to 0.87), and 0.57 (95% CI 0.41 to 0.79) across increasing quintiles of PA compared with the lowest quintile.<sup>27</sup>
- A 2003 meta-analysis of 23 studies on the association of PA with stroke indicated that compared with low levels of activity, high (RR 0.79, 95% CI 0.69 to 0.91) and moderate (RR 0.91, 95% CI 0.80 to 1.05) levels of activity were inversely associated with the likelihood of developing total stroke (ischemic and hemorrhagic).<sup>28</sup>

### Secondary Prevention

- PA improves inflammatory markers in people with existing stable CHD. After a 6-week training session, C-reactive protein levels declined by 23.7% ( $P<0.001$ ), and plasma vascular cell adhesion molecule-1 levels declined by 10.23% ( $P<0.05$ ); there was no difference in leukocyte count or levels of intercellular adhesion molecule-1.<sup>29</sup>
- In a randomized trial of patients with PAD, supervised treadmill exercise training and lower-extremity resistance training were each associated with significant improvements in functional performance and quality of life compared with a usual-care control group. Exercise training was additionally associated with improved brachial artery flow-mediated dilation, whereas resistance training was associated with better stair-climbing ability versus control.<sup>30</sup>
- The benefit of intense exercise training for cardiac rehabilitation in people with HF was tested in a trial of 27 patients with stable, medically treated HF. Intense activity (an aerobic interval-training program 3 times per week for 12 weeks) was associated with a significant 35% improvement in left ventricular EF and decreases in pro-brain natriuretic peptide (40%), left ventricular end-diastolic volume (18%), and left ventricular end-systolic volume (25%) compared with control and endurance-training groups.<sup>31</sup>

### Costs

- The economic consequences of physical inactivity are substantial. In a summary of WHO data sources, the economic costs of physical inactivity were estimated to account for 1.5% to 3.0% of total direct healthcare expenditures in developed countries such as the United States.<sup>32</sup>
- The 1996 MEPS was linked to self-reported activity in the 1995 NHIS. On the basis of a self-reported prevalence of inactivity of 47.5% and a prevalence of CVD of 21.5%, the direct expenditures for CVD associated with inactivity were estimated to be \$23.7 billion in 2001.<sup>33</sup>

**Table 14-1. Regular Leisure-Time Physical Activity**

Population Group	Prevalence, 2008 (Age $\geq 18$ y), %
Both sexes	34.9
Men	37.4
Women	32.7
NH white only	38.1
NH black only	29.3
Hispanic or Latino	27.8
American Indian/Alaska Native only	34.0
Asian only	28.3

NH indicates non-Hispanic.

Regular leisure-time physical activity is defined as light to moderate activity for  $\geq 30$  minutes, 5 times per week, or vigorous activity for  $\geq 20$  minutes,  $\geq 3$  times per week.

Data are age adjusted for adults  $\geq 18$  years of age.

Source: National Health Interview Survey 2009 (National Center for Health Statistics).<sup>7</sup>

**Chart 14-1.** Prevalence of students in grades 9–12 who met currently recommended levels of physical activity during the past 7 days by race/ethnicity and sex (Youth Risk Behavior Surveillance: 2009). “Currently recommended levels” was defined as activity that increased their heart rate and made them breathe hard some of the time for a total of at least 60 minutes per day on 5 of the 7 days preceding the survey. NH indicates non-Hispanic. Data derived from *MMWR Surveillance Summaries*.<sup>1</sup>

**Chart 14-2.** Prevalence of regular leisure-time physical activity among adults >18 years of age by race/ethnicity and sex (National Health Interview Survey: 2009). Percentages are age-adjusted. “Regular leisure-time physical activity” was defined as  $\geq 3$  sessions per week of vigorous activity lasting at least 20 minutes or  $\geq 5$  sessions per week of light or moderate activity lasting at least 30 minutes. NH indicates non-Hispanic. Data derived from Pleis et al.<sup>7</sup>

**Chart 14-3.** Prevalence of students in grades 9 to 12 who did not participate in at least 60 minutes of physical activity on any day by race/ethnicity and sex (Youth Risk Behavior Surveillance: 2009). NH indicates non-Hispanic. Data derived from *MMWR Surveillance Summaries*.<sup>1</sup>

**Chart 14-4.** Prevalence of children 6 to 19 years of age who attained sufficient moderate to vigorous physical activity to meet public health recommendations ( $\geq 60$  minutes per day on  $\geq 5$  of the 7 days preceding the survey), by sex and age (National Health and Nutrition Examination Survey: 2003–2004). Data derived from Troiano et al.<sup>3</sup>

## 15. Risk Factor: Overweight and Obesity

See Table 15-1 and Charts 15-1 through 15-3.

### Prevalence

#### Youth

- The prevalence of overweight and obesity in children 2 to 5 years of age, based on a BMI-for-age value  $\geq 85$ th percentile of the 2000 CDC growth charts, was 16% for non-Hispanic white boys and 20% for non-Hispanic white girls, 28% for non-Hispanic black boys and 24% for non-Hispanic black girls, and 32% for Mexican American boys and 23% for Mexican American girls according to 2007 to 2008 data from NHANES (NCHS). In children 6 to 11 years of age, the prevalence was 35% for non-Hispanic white boys and 34% for non-Hispanic white girls, 36% for non-Hispanic black boys and 39% for non-Hispanic black girls, and 44% for Mexican American boys and 39% for Mexican American girls. In children 12 to 19 years of age, the prevalence was 33% for non-Hispanic white boys and 30% for non-Hispanic white girls, 33% for non-Hispanic black boys and 46% for non-Hispanic black girls, and 46% for Mexican American boys and 42% for Mexican American girls.<sup>1</sup>
- The prevalence of obesity in children 2 to 5 years of age, based on BMI-for-age values  $\geq 95$ th percentile of the 2000 CDC growth charts, was 7% for non-Hispanic white boys and 12% for non-Hispanic white girls, 11% for non-Hispanic black boys and 12% for non-Hispanic black girls, and 19% for Mexican American boys and 8% for Mexican American girls according to 2007 to 2008 data from NHANES (NCHS). In children 6 to 11 years of age, the prevalence was 21% for non-Hispanic white boys and 17%

for non-Hispanic white girls, 18% for non-Hispanic black boys and 21% for non-Hispanic black girls, and 27% for Mexican American boys and 22% for Mexican American girls. In children 12 to 19 years of age, the prevalence was 17% for non-Hispanic white boys and 15% for non-Hispanic white girls, 20% for non-Hispanic black boys and 29% for non-Hispanic black girls, and 27% for Mexican American boys and 17% for Mexican American girls.<sup>1</sup>

- Overall, 19% of US children and adolescents 6 to 19 years of age have BMI-for-age values  $\geq 95$ th percentile of the 2000 CDC growth charts for the United States (NHANES [2007–2008], NCHS).<sup>1</sup>
- NHANES 2003 to 2006 found that 11.3% of children and adolescents 2 to 19 years of age were at or above the 97th percentile of the 2000 BMI-for-age growth chart, 16.3% were  $\geq 95$ th percentile, and 31.9% were  $\geq 85$ th percentile.<sup>2</sup>
- Data from the NHANES in the 2008 National Healthcare Quality Report found that<sup>3</sup>:
  - During 2003 to 2006, 39.4% of overweight ( $\geq 95$ th percentile of the 2000 BMI-for-age growth chart) children and teens 2 to 19 years of age were told by a doctor or health professional that they were overweight.
  - During 2003 to 2006, overweight children 2 to 5 years of age (22.3%) and 6 to 11 years of age (35.70%) were less likely than overweight children 12 to 19 years of age (47.5%) to be told by a provider that they were overweight.
- A study of >8500 4-year-olds in the Early Childhood Longitudinal Study, Birth Cohort (National Center for Education Statistics) found that 1 in 5 are obese. Almost 13% of Asian children, 16% of white children, nearly 21% of black children, 22% of Hispanic children, and 31% of American Indian children were obese. Children were considered obese if their BMI was  $\geq 95$ th percentile, based on CDC BMI growth charts. For 4-year-olds, that would be a BMI of  $\approx 18$  kg/m<sup>2</sup>. Researchers did not examine reasons for the disparities.<sup>4</sup>
- Overweight adolescents have a 70% chance of becoming overweight adults. This increases to 80% if 1 or both parents are overweight or obese.<sup>5</sup>
- Childhood sociodemographic factors may contribute to sex disparities in obesity prevalence. A study of data from the National Longitudinal Study of Adolescent Health found that parental education consistently modified sex disparity in blacks. The sex gap was largest in those with low parental education (16.7% of men compared with 45.4% of women were obese) and smallest in those with high parental education (28.5% of men compared with 31.4% of women were obese). In whites, there was little overall sex difference in obesity prevalence.<sup>6</sup>
- The obesity epidemic is disproportionately more rampant among children living in low-income, low-education, and higher-unemployment households according to data from the National Survey of Children's Health.<sup>7</sup>

### Abbreviations Used in Chapter 15

BMI	body mass index
BP	blood pressure
BRFSS	Behavioral Risk Factor Surveillance System
CDC	Centers for Disease Control and Prevention
CI	confidence interval
CVD	cardiovascular disease
DM	diabetes mellitus
FHS	Framingham Heart Study
kg/m <sup>2</sup>	kilograms per square meter
MESA	Multi-Ethnic Study of Atherosclerosis
NCHS	National Center for Health Statistics
NHANES	National Health and Nutrition Examination Survey
NHIS	National Health Interview Survey
NHLBI	National Heart, Lung, and Blood Institute
NINDS	National Institute of Neurological Disorders and Stroke
NOMAS	Northern Manhattan Study
OR	odds ratio
PA	physical activity
RR	relative risk
WHO	World Health Organization

### Adults

- Overall, 68% of US adults were overweight or obese (72% of men and 64% of women).<sup>8</sup>

- Among men, Mexican-Americans (80%) and non-Hispanic whites (73%) were more likely to be overweight or obese than non-Hispanic blacks (69%) according to NHANES 2007 to 2008.<sup>8</sup>
- Among women, non-Hispanic blacks (78%) and Mexican-Americans (77%) were more likely to be overweight or obese than non-Hispanic whites (61%).<sup>8</sup>
- Of US adults, 34% were obese (32% of men and 36% of women) according to NHANES 2007 to 2008.<sup>8</sup>
- Among men, non-Hispanic blacks (37%) and Mexican-Americans (36%) were more likely to be obese than non-Hispanic whites (32%).<sup>8</sup>
- Among women, non-Hispanic blacks (50%) and Mexican-Americans (45%) were more likely to be obese than non-Hispanic whites (33%).<sup>8</sup>
- When estimates were based on self-reported height and weight in the BRFSS/CDC survey in 2008, the prevalence of obesity ranged from 19.1% in Colorado to 33.3% in Mississippi. The median percentage by state was 26.6%. Additionally, no state met the Healthy People 2010 goal of reducing obesity to 15% of adults.<sup>9</sup>
- The county-level prevalence of obesity in the United States ranged from 12.4% to 43.7% with a median of 28.4% according to BRFSS/CDC 2007.<sup>10</sup>
- In 1998 and 1999, surveys of people in 8 states and the District of Columbia by the BRFSS study of the CDC indicated that obesity rates were significantly higher among people with disabilities, especially blacks and those 45 to 64 years of age.<sup>11</sup>
- Blacks  $\geq 18$  years of age (27.6%), American Indians or Alaska Natives (29.1%), and whites (35.9%) were less likely than Asians (53.4%) to be at a healthy weight based on self-reported height and weight data from the 2009 NHIS.<sup>12</sup>
- Based on self-reported weights and heights, data showed that blacks  $\geq 18$  years of age (37.6%) and American Indians or Alaska Natives (34.4%) were more likely to be obese than were whites (26.6%) and Asians (9.0%) according to 2009 data from the NHIS.<sup>12</sup>
- Most adults in Asian subgroups were in the healthy weight range, with rates ranging from 51% for Filipino adults to 68% for Chinese adults. Although the prevalence of obesity is low within the Asian adult population, Filipino adults (14%) were more than twice as likely to be obese (BMI  $\geq 30$  kg/m<sup>2</sup>) as Asian Indian (6%), Vietnamese (5%), or Chinese (4%) adults.<sup>13</sup>
- From 1999 to 2004, obese adults 45 to 64 years of age (73%) and  $\geq 65$  years of age (73.6%) were more likely than those 20 to 44 years of age (59.5%) to be told by a doctor or health professional that they were overweight. Obese adults 45 to 64 years of age and  $\geq 65$  years of age were more likely to receive advice about exercise than those 18 to 44 years of age.<sup>3</sup>
- Approximately 64.8% of obese adults were told by a doctor or health professional that they were overweight according to the 2008 National Healthcare Disparities Report (based on NHANES 2003 to 2006).<sup>14</sup>
- The proportion of obese adults told that they were overweight was significantly lower for non-Hispanic blacks (60.5%) and Mexican Americans (57.1%) than for non-Hispanic whites (66.4%), for middle-income people than for high-income people (62.4% versus 70.6%), and for adults with less than a high school education than for those with any college education (59.2% versus 70.3%).<sup>14</sup>
- A large proportion of white, black, and Hispanic participants were overweight (60% to 85%) or obese (30% to 50%), whereas fewer Chinese American participants were overweight (33%) or obese (5%), as judged by an analysis of data from MESA. These findings may be indicators of potential future increases in vascular disease burden and healthcare costs associated with the obesity epidemic.<sup>15</sup>

## Trends

### Youth

- The prevalence of BMI-for-age values  $\geq 95$ th percentile of the 2000 CDC growth charts in children 6 to 11 years of age was 20% in 2007 to 2008 compared with 4.0% in 1971 to 1974. The prevalence of BMI-for-age values  $\geq 95$ th percentile in adolescents 12 to 19 years of age was 18% in 2007 to 2008 compared with 6% in 1971 to 1974 in NHANES. No statistically significant linear trends in high weight for recumbent length or high BMI were found over the time periods 1999 to 2000, 2001 to 2002, 2003 to 2004, 2005 to 2006, and 2007 to 2008 among girls and boys except among the very heaviest 6- through 19-year-old boys.<sup>1</sup>
- Among infants and children between 6 and 23 months years of age, the prevalence of high weight for age was 7% in 1976 to 1980 and 12% in 2003 to 2006 (NHANES, NCHS).<sup>16</sup>
- The obesity epidemic in children continues to grow on the basis of recent data from the Bogalusa Heart Study. Compared with 1973 to 1974, the proportion of children 5 to 17 years of age who were obese was 5 times higher in 2008 to 2009.<sup>17</sup>

### Adults

- Analysis of the FHS, 1971 to 2001 (NHLBI), showed that among normal-weight white adults between 30 and 59 years of age, the 4-year rates of developing overweight varied from 14% to 19% in women and from 26% to 30% in men. The 30-year risk was similar for both sexes, with some variation by age. Overall, the 30-year risk for “overweight or more” exceeded 1 in 2 people, 1 in 4 for obesity, and 1 in 10 for stage II obesity (BMI  $\geq 35$  kg/m<sup>2</sup>) across different age groups. The 30-year estimates correspond to the lifetime risk for “overweight or more” or obesity for participants 50 years of age.<sup>18</sup>
- The age-adjusted prevalence of obesity among adults increased between 1976 to 1980 and 1988 to 1994 and again between 1988 to 1994 and 1999 to 2000 based on NHANES data. Over the 10-year period of 1999 to 2008, obesity showed no significant trend among women. For men, there was a significant linear trend. Obesity prevalence for men was 28% in NHANES 1999 to 2000 (NCHS) and 32% in NHANES 2007 to 2008; for women, obesity prevalence was 33% in 1999 to 2000 and 36% in 2007 to 2008.<sup>8</sup>

- Thirty-five percent of noninstitutionalized women 65 to 74 years of age and 27% of women  $\geq 75$  years of age were obese on the basis of NHANES/NCHS data in 2007 to 2008. This is an increase from 1988 to 1994, when 27% of women 65 to 74 years of age and 19% of women  $\geq 75$  years of age were obese. For men, from 1988 to 1994, 24% of those 65 to 74 years of age and 13% of those  $\geq 75$  years of age were obese compared with 40% of those 65 to 74 years of age and 26% of those  $\geq 75$  years of age in 2007 to 2008.<sup>19</sup>
- The prevalence of obesity increased by 5.6% or  $\approx 2.7$  million from 1997 to 2002 in Medicare beneficiaries. By 2002, 21.4% of beneficiaries and 39.3% of disabled beneficiaries were obese compared with 16.4% and 32.5%, respectively, in 1997. The rise in obesity, along with expansions in treatment coverage, could greatly increase obesity-related Medicare spending.<sup>20</sup>
- The WHO estimates that by 2015, the number of overweight people globally will increase to 2.3 billion, and 700 million will be obese. Globally, at least 20 million children  $< 5$  years of age were overweight in 2005. Once considered a problem only in high-income countries, overweight and obesity are now dramatically on the rise in low- and middle-income countries, particularly in urban settings.<sup>21</sup>

### Morbidity

- Overweight children and adolescents are at increased risk for future adverse health effects, including<sup>22</sup>:
  - Increased prevalence of traditional cardiovascular risk factors such as hypertension, hyperlipidemia, and DM.
  - Poor school performance, tobacco use, alcohol use, premature sexual behavior, poor diet, and DM.
  - Other associated health conditions such as asthma, hepatic steatosis, sleep apnea, stroke, some cancers (breast, colon, and kidney), musculoskeletal disorders, and gallbladder disease.
- The increasing prevalence of obesity is driving an increased incidence of type 2 DM. Data from the FHS indicate a doubling in the incidence of DM over the past 30 years, most dramatically during the 1990s and primarily among individuals with a BMI  $> 30$  kg/m<sup>2</sup>.<sup>23</sup>
- Obesity was the most powerful predictor of DM in the Nurses' Health Study. Women with a BMI of  $\geq 35$  kg/m<sup>2</sup> had an RR for DM of 38.8 compared with women with a BMI of  $< 23$  kg/m<sup>2</sup>.<sup>24</sup>
- Overweight and obesity were associated with increased risk for cardiovascular disease in the FHS. The age-adjusted relative risk for CVD was increased by 21% in men and 20% in women among those who were overweight and 46% in men and 64% in women among those who were obese.<sup>25</sup>
- Abdominal obesity is an independent risk factor for ischemic stroke in all race/ethnic groups. This effect is larger for those  $< 65$  years of age (OR, 4.4) than for those  $> 65$  years of age (OR, 2.2; NOMAS, NINDS).<sup>26</sup>
- A recent comparison of risk factors in both the Honolulu Heart Program and FHS (NHLBI) showed that a BMI increase of  $\approx 3$  kg/m<sup>2</sup> raised the risk of hospitalized thromboembolic stroke by 10% to 30%.<sup>27</sup>
- Obesity is also a strong predictor of sleep-disordered breathing, itself strongly associated with the development of CVD, as well as with myriad other health conditions, including numerous cancers, nonalcoholic fatty liver disease, gallbladder disease, musculoskeletal disorders, and reproductive abnormalities.<sup>28</sup>

### Mortality

- Elevated childhood BMIs in the highest quartile were associated with premature death as an adult in a cohort of 4857 American Indian children during a median follow-up of 23.9 years.<sup>29</sup>
- Among adults, obesity was associated with nearly 112 000 excess deaths (95% CI, 53 754 to 170 064) relative to normal weight in 2000. Grade I obesity (BMI, 30 to  $< 35$  kg/m<sup>2</sup>) was associated with almost 30 000 of these excess deaths (95% CI, 8534 to 68 220) and grade II to III obesity (BMI  $\geq 35$  kg/m<sup>2</sup>) with  $> 82$  000 (95% CI, 44 843 to 119 289). Underweight was associated with nearly 34 000 excess deaths (95% CI, 15 726 to 51 ). As other studies have found,<sup>30</sup> overweight (BMI, 25 to  $< 30$  kg/m<sup>2</sup>) was not associated with excess deaths.<sup>31</sup>
- Overweight was associated with significantly increased mortality resulting from DM or kidney disease and was not associated with increased mortality resulting from cancer or CVD in an analysis of 2004 data from NHANES. Obesity was associated with significantly increased mortality caused by CVD, some cancers, and DM or kidney disease. Obesity was associated with 13% of CVD deaths in 2004.<sup>32</sup>
- Data from NHANES 1988 to 1994 were studied to determine estimates of excess deaths associated with BMI and other anthropometric variables. Estimates for all-cause mortality, obesity-related causes of death, and other causes of death showed no statistically significant or systematic differences between BMI and other variables.<sup>33</sup>
- In a collaborative analysis of data from almost 900 000 adults in 57 prospective studies, mostly in Western Europe and North America, overall mortality was lowest at  $\approx 22.5$  to 25 kg/m<sup>2</sup> in both sexes and at all ages, after exclusion of early follow-up and adjustment for smoking status. Above this range, each 5-kg/m<sup>2</sup>-higher BMI was associated with  $\approx 30\%$  higher all-cause mortality, and no specific cause of death was inversely associated with BMI. Below 22.5 to 25 kg/m<sup>2</sup>, the overall inverse association with BMI was due predominantly to strong inverse associations for smoking-related respiratory disease, and the only clearly positive association was for ischemic heart disease.<sup>34</sup>
- Overweight and obesity were associated with large decreases in life expectancy in an analysis of data from FHS (NHLBI). Forty-year-old female nonsmokers lost 3.3 years and 40-year-old male nonsmokers lost 3.1 years of life expectancy because of overweight. In 40-year-old nonsmokers, women lost 7.1 years and men lost 5.8 years because of obesity. Obese female smokers lost 7.2 years

and obese male smokers lost 6.7 years compared with normal-weight nonsmokers.<sup>35</sup>

- Recent calculations based on NHANES data from 1978 to 2006 suggest that the gains in life expectancy from smoking cessation are beginning to be outweighed by the loss of life expectancy from obesity.<sup>36</sup>
- As a result of the increasing prevalence of obesity, the number of quality-adjusted life years lost as a result of obesity is similar to or greater than that lost as a result of smoking based on data from the BRFSS.<sup>37</sup>
- Recent estimates suggest that reductions in smoking, cholesterol, BP, and PA levels resulted in a gain of 2 770 500 life-years. However, these gains were reduced by a loss of 715 000 life-years owing to the increased prevalence of obesity and DM.<sup>38</sup>

### Cost

- Among children and adolescents, annual hospital costs related to obesity were \$127 million between 1997 and 1999.<sup>39</sup>
- According to 1 study, overall estimates show that the annual medical burden of obesity has increased to almost 10% of all medical spending and could amount to \$147 billion per year in 2008 (in 2008 dollars).<sup>40</sup>
- If current trends in the growth of obesity continue, total healthcare costs attributable to obesity could reach \$861 to \$957 billion by 2030, which would account for 16% to 18% of US health expenditures.<sup>41</sup>
- The total excess cost related to the current prevalence of adolescent overweight and obesity is estimated to be \$254 billion, \$208 billion in lost productivity secondary to premature morbidity and mortality, and \$46 billion in direct medical costs.<sup>42</sup>

NH indicates non-Hispanic. Ellipses ( . . . ) indicate data not available. Data for white and black males and females are for non-Hispanics. Overweight and obesity in adults is body mass index  $\geq$ 25 kg/m<sup>2</sup>. Obesity in adults is  $\geq$  body mass index 30 kg/m<sup>2</sup>. In children, overweight and obesity are based on body mass index -for-age values  $\geq$ 85th percentile of the 2000 Centers for Disease Control and Prevention growth charts. In children, obesity is based on body mass index -for-age values  $\geq$ 95th percentile of the Centers for Disease Control and Prevention growth charts.

In January 2007, the American Medical Association's Expert Task Force on Childhood Obesity recommended new definitions for overweight and obesity in children and adolescents (available at [http://www.ama-assn.org/ama1/pub/upload/mm/433/ped\\_obesity\\_recs.pdf](http://www.ama-assn.org/ama1/pub/upload/mm/433/ped_obesity_recs.pdf)). However, statistics based on this new definition are not yet available.

\*Data from Health Affairs.<sup>40</sup>

Sources: age-adjusted National Health and Nutrition Examination Survey 2005–2008 (National Center for Health Statistics), National Heart, Lung, and Blood Institute, and unpublished data. Estimates from National Health and Nutrition Examination Survey 2005–2008 (National Center for Health Statistics) were applied to 2008 population estimates. In children, age-adjusted National Health and Nutrition Examination Survey 2007–2008 data were applied to 2006 population estimates (*JAMA*. 2010;303:235–241; and *JAMA*. 2010;303:242–249).

**Chart 15-1.** Prevalence of overweight and obesity among students in grades 9 through 12 by sex and race/ethnicity. NH indicates non-Hispanic. Data derived from Youth Risk Behavior Surveillance—United States, 2009, Table 90.<sup>43</sup>

**Chart 15-2.** Age-adjusted prevalence of obesity in adults 20 to 74 years of age by sex and survey year (National Health Examination Survey: 1960–1962; National Health and Nutrition Examination Survey: 1971–1975, 1976–1980, 1988–1994, 1999–2002, and 2003–2006). Obesity is defined as a body mass index of  $\geq 30.0$  kg/m<sup>2</sup>. Data derived from Health, United States, 2009 (National Center for Health Statistics).<sup>44</sup>

**Chart 15-3.** Trends in the prevalence of overweight among US children and adolescents by age and survey year (National Health and Nutrition Examination Survey: 1976–1980, 1988–1994, 1999–2002, and 2003–2006). Data derived from Health, United States, 2009 (National Center for Health Statistics).<sup>44</sup>

## 16. Risk Factor: Diabetes Mellitus

ICD-9 250; ICD-10 E10–E14. See Table 16-1 and Charts 16-1 through 16-4.

### Prevalence

#### Youth

- In SEARCH, the prevalence of DM in youths <20 years of age in 2001 in the United States was 1.82 cases per 1000

#### Abbreviations Used in Chapter 16

ACS	acute coronary syndrome
AHRQ	Agency for Healthcare Research and Quality
AMI	acute myocardial infarction
ARIC	Atherosclerosis Risk in Communities study
BMI	body mass index
BP	blood pressure
BRFSS	Behavioral Risk Factor Surveillance System
CDC	Centers for Disease Control and Prevention
CHD	coronary heart disease
CHS	Cardiovascular Health Study
CI	confidence interval
CVD	cardiovascular disease
DM	diabetes mellitus
FHS	Framingham Heart Study
HbA <sub>1c</sub>	glycosylated hemoglobin
HD	heart disease
HR	hazard ratio
ICD	<i>International Classification of Diseases</i>
kg/m <sup>2</sup>	kilograms per square meter
LDL	low-density lipoprotein
mg/dL	milligrams per deciliter
MESA	Multi-Ethnic Study of Atherosclerosis
MI	myocardial infarction
mm Hg	millimeter of mercury
NCHS	National Center for Health Statistics
NHANES	National Health and Nutrition Examination Survey
NHDS	National Hospital Discharge Survey
NHIS	National Health Interview Survey
NHLBI	National Heart, Lung, and Blood Institute
NIDDK	National Institute of Diabetes and Digestive and Kidney Diseases
NIH	National Institutes of Health
NINDS	National Institute of Neurological Disorders and Stroke
NSTEMI	non–ST-segment–elevation myocardial infarction
OR	odds ratio
PA	physical activity
RR	relative risk
SBP	systolic blood pressure
SEARCH	Search for Diabetes in Youth Study
STEMI	ST-segment–elevation myocardial infarction
TIMI	Thrombolysis in Myocardial Infarction
UA	unstable angina

youths (0.79 per 1000 among youths 0 to 9 years of age and 2.80 per 1000 among youths 10 to 19 years of age). Non-Hispanic white youths had the highest prevalence (1.06 per 1000) in the younger group. Among youths 10 to 19 years of age, black youths (3.22 per 1000) and non-Hispanic white youths (3.18 per 1000) had the highest rates, followed by American Indian youths (2.28 per 1000), Hispanic youths (2.18 per 1000), and Asian/Pacific Islander youths (1.34 per 1000). Among younger children, type 1 DM accounted for  $\geq 80\%$  of DM; among older youths, the proportion of type 2 DM ranged from 6% (0.19 per 1000 for non-Hispanic white youths) to 76% (1.74 per 1000 for American Indian youths). This translates to 154 369 youths with physician-diagnosed DM in 2001 in the United States, for an overall prevalence estimate for DM in children and adolescents of  $\approx 0.18\%$ .<sup>1</sup>

- Approximately 186 000 people <20 years of age have DM. Each year,  $\approx 15$  000 people <20 years of age are diagnosed with type 1 DM. Healthcare providers are finding more and more children with type 2 DM, a disease usually diagnosed in adults  $\geq 40$  years of age. Children who develop type 2 DM are typically overweight or obese and have a family history of the disease. Most are American Indian, black, Asian, or Hispanic/Latino.<sup>2</sup>
- Among adolescents 10 to 19 years of age diagnosed with DM, 57.8% of blacks were diagnosed with type 2 versus type 1 DM compared with 46.1% of Hispanic and 14.9% of white youths.<sup>3</sup>
- According to the Bogalusa Heart Study, a long-term follow-up study of youths aging into adulthood, youths who were prediabetic or who had DM are more likely to have a constellation of metabolic disorders in young adulthood (19 to 44 years of age), including obesity, hypertension, dyslipidemia, and metabolic syndrome, all of which predispose to CHD.<sup>4</sup>

#### Adult

- On the basis of data from NHANES 2005 to 2008 (NCHS; unpublished NHLBI tabulation) (Table 16-1), an estimated 18 300 000 Americans  $\geq 20$  years of age have physician-diagnosed DM. An additional 7 100 000 adults have undiagnosed DM and about 81 500 000 adults have prediabetes (eg, fasting blood glucose of 100 to <126 mg/dL). The prevalence of prediabetes in the US adult population is nearly 37%.
- Data from NHANES 2005 to 2006 (NCHS) showed the prevalence of diagnosed DM in adults  $\geq 65$  years of age to be 17.0%. The prevalence of undiagnosed DM was 14.6% (based on fasting glucose or oral glucose tolerance testing).<sup>5</sup>
- Among Americans  $\geq 20$  years of age, 7.7% have diagnosed DM. Women  $\geq 20$  years of age have a slightly higher prevalence (8.3%) than men (7.2%) (NHANES) (NCHS).<sup>5</sup>
- Data from NHANES (NCHS) show a disproportionately high prevalence of DM in non-Hispanic blacks compared with non-Hispanic whites.<sup>5</sup>
- After adjustment for population age differences, 2004 to 2006 national survey data for people  $\geq 20$  years of age indicate that 6.6% of non-Hispanic whites, 7.5% of Asian

- Americans, 10.4% of Hispanics, and 11.8% of non-Hispanic blacks had diagnosed DM.<sup>6</sup>
- In 2004 to 2006, the prevalence of diagnosed DM was more than twice as high for Asian Indian adults (14%) as for Chinese (6%) or Japanese (5%) adults.<sup>7</sup>
  - Type 2 DM accounts for 90% to 95% of all diagnosed cases of DM in adults.<sup>8</sup> In Framingham, MA, 99% of DM is type 2.<sup>9</sup>
  - The prevalence of DM increased by 8.2% from 2000 to 2001. From 1990 to 2001, the prevalence of those diagnosed with DM increased 61%.<sup>10</sup>
  - On the basis of 2009 BRFSS (CDC) data, the prevalence of adults who reported ever having been told by a physician that they had DM ranged from 5.8% in Alaska and Colorado to 12.4% in West Virginia. The median percentage among states was 8.3%.<sup>11</sup>
  - The CDC analyzed data from 1994 to 2004 collected by the Indian Health Service that indicated that the age-adjusted prevalence per 1000 population of DM increased 101.2% among American Indian/Alaska Native adults <35 years of age (from 8.5% to 17.1%). During this time period, the prevalence of diagnosed DM was greater among females than males in all age groups.<sup>12</sup>
  - The prevalence of DM for all age groups worldwide was estimated to be 2.8% in 2000 and is projected to be 4.4% in 2030. The total number of people with DM is projected to rise from 171 million in 2000 to 366 million in 2030.<sup>13</sup>
  - On the basis of projections from NHANES/NCHS studies between 1984 and 2004, the total prevalence of DM in the United States is expected to more than double from 2005 to 2050 (from 5.6% to 12.0%) in all age, sex, and race/ethnicity groups. Increases are projected to be largest for the oldest age groups (for instance, increasing by 220% among those 65 to 74 years of age and by 449% among those ≥75 years of age). DM prevalence is projected to increase by 99% among non-Hispanic whites, by 107% among non-Hispanic blacks, and by 127% among Hispanics. The age/race/ethnicity group with the largest increase is expected to be blacks ≥75 years of age (increase of 606%).<sup>14</sup>

## Incidence

### Youths

- In the SEARCH study, the incidence of DM in youths overall was 24.3 per 100 000 person-years. Among children <10 years of age, most had type 1 DM, regardless of race/ethnicity. The highest rates of incident type 1 DM were observed in non-Hispanic white youths (18.6, 28.1, and 32.9 per 100 000 person-years for age groups of 0 to 4, 5 to 9, and 10 to 14 years, respectively). Overall, type 2 DM was relatively infrequent, with the highest rates (17.0 to 49.4 per 100 000 person-years) seen among 15- to 19-year-old minority groups.<sup>3</sup>

### Adults

- A total of 1 600 000 new cases of DM were diagnosed in people ≥20 years of age in 2006.<sup>6</sup>

- Data from Framingham, MA, indicate a doubling in the incidence of DM over the past 30 years, most dramatically during the 1990s. Among adults 40 to 55 years of age in each decade of the 1970s, 1980s, and 1990s, the age-adjusted 8-year incidence rates of DM were 2.0%, 3.0%, and 3.7% among women and 2.7%, 3.6%, and 5.8% among men, respectively. Compared with the 1970s, the age- and sex-adjusted OR for DM was 1.40 in the 1980s and 2.05 in the 1990s (*P* for trend=0.0006). Most of the increase in absolute incidence of DM occurred in individuals with a BMI ≥30 kg/m<sup>2</sup> (*P* for trend=0.03).<sup>15</sup>
- DM incidence in adults also varies markedly by race. Over 5 years of follow-up in 45- to 84-year-olds in the MESA, 8.2% of the cohort developed DM. The cumulative incidence was highest in Hispanics (11.3%), followed by black (9.5%), Chinese (7.7%), and white (6.3%) participants.<sup>16</sup>

## Mortality

DM mortality in 2007 was 71 382. Any-mention mortality in 2007 was 231 402 (NHLBI tabulation of NCHS mortality data).

- The 2007 overall underlying-cause death rate owing to DM was 22.5. Death rates per 100 000 people were 24.6 for white males, 45.9 for black males, 17.2 for white females, and 40.2 for black females (NCHS, Health Data Interactive Web site <http://www.cdc.gov/nchs/hdi>; accessed July 19, 2010).
- According to data from the National Diabetes Information Clearinghouse, the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK), and the National Institutes of Health (NIH):
  - At least 65% of people with DM die of some form of HD or stroke.
  - HD death rates among adults with DM are 2 to 4 times higher than the rates for adults without DM.<sup>17</sup>
- FHS/NHLBI data show that having DM significantly increased the risk of developing CVD (HR, 2.5 for women and 2.4 for men) and of dying when CVD was present (HR, 2.2 for women and 1.7 for men). Diabetic men and women ≥50 years of age lived an average of 7.5 and 8.2 years less than their nondiabetic equivalents. The differences in life expectancy free of CVD were 7.8 and 8.4 years, respectively.<sup>18</sup>
- Analysis of data from NHANES 1971 to 2000 found that men with DM experienced a 43% relative reduction in the age-adjusted mortality rate, which is similar to that of nondiabetic men. Among women with DM, however, mortality rates did not decrease, and the difference in mortality rates between diabetic and nondiabetic women doubled.<sup>19</sup>
- During 1979 to 2004, DM death rates for black youths 1 to 19 years of age were approximately twice those for white youths. During 2003 to 2004, the annual average DM death rate per 1 million youths was 2.46 for black youths and 0.91 for white youths.<sup>20</sup>
- Analysis of data from the FHS from 1950 to 2005 found reductions in all-cause and CVD mortality among men and women with and without DM. However, all-cause and CVD mortality rates among individuals with DM remain ≈2-fold higher compared with individuals without DM.<sup>21</sup>

## Awareness

- The NIDDK estimates that 23.6 million Americans (7.8% of the population) have DM.<sup>6</sup>
- Analysis of NHANES/NCHS data from 1988 to 1994 to 1999 to 2005 to 2006 in adults  $\geq 20$  years of age showed that 40% of those with DM did not know they had it.<sup>5</sup> Although the prevalence of diagnosed DM has increased significantly over the past decade, the prevalences of undiagnosed DM and impaired fasting glucose have remained relatively stable. Minority groups remain disproportionately affected.<sup>22</sup>
- Analysis of NHANES/NCHS data collected during 2005 to 2008 indicated that the prevalence of DM was 8.2% among people  $\geq 20$  years of age. Prevalence of DM was defined as people who were told by a physician or other health professional that they have DM. Of the estimated 18 300 adults with DM, 73.3% were told or were on treatment and 26.7% (5.7 million) were unaware of the diagnosis. Of 7 895 000 people being treated (37.3% of the diabetic population), one third of them (2 604 000) were controlled (ie, on treatment with fasting plasma glucose  $< 126$  mg/dL) and 25.0% (5 300 000) were treated and uncontrolled (fasting plasma glucose  $\geq 126$  mg/dL). An estimated 13 300 000 individuals with DM are not treated. The untreated and unaware population (5 600 000) was 26.7% of the diabetic population (NHLBI tabulation of NHANES 2003 to 2006) (see Chart 16-4).

## Aftermath

- Although the exact date of DM onset can be difficult to determine, duration of DM appears to affect CVD risk. Longitudinal data from Framingham, MA, suggest that the risk factor-adjusted relative risk of CHD was 1.38 (95% CI, 0.99 to 1.92) times higher and the risk for CHD death was 1.86 (95% CI, 1.17 to 2.93) times higher for each 10-year increase in duration of DM.<sup>23</sup>
- DM increases the risk of stroke, with the RR ranging from 1.8 to almost 6.0.<sup>24</sup>
- Ischemic stroke patients with DM are younger, more likely to be black, and more likely to have hypertension, MI, and high cholesterol than nondiabetic patients. DM increases ischemic stroke incidence at all ages, but this risk is most prominent before 55 years of age in blacks and before 65 years of age in whites.<sup>25</sup>
- On the basis of data from the NCHS/NHIS, 1997 to 2005:<sup>26</sup>
  - During 1997 to 2005, the estimated number of people  $\geq 35$  years of age with DM with a self-reported cardiovascular condition increased 36%, from 4.2 million in 1997 to 5.7 million in 2005. However, the age-adjusted prevalence of self-reported CVD conditions among people with diagnosed DM  $\geq 35$  years of age decreased 11.2%, from 36.6% in 1997 to 32.5% in 2005.
  - During 1997 to 2005, age-adjusted CVD prevalence was higher among men than women, among whites than blacks, and among non-Hispanics than Hispanics. Among women, the age-adjusted prevalence decreased by 11.2%; among men, it did not decrease significantly.

Among blacks, the age-adjusted prevalence of self-reported CVD decreased by 25.3%; among whites, no significant decrease occurred; among non-Hispanics, the rate decreased by 12%. No clear trends were detected among Hispanics. If the total number of people with DM and self-reported CVD increased over this period but proportions with self-reported CVD declined, the data suggest that the mean age at which people have been diagnosed is decreasing, or the higher CVD mortality rate among older diabetic individuals is removing them from ability to self-report CVD. These and other data show a consistent increase over time in the United States of the number of people with DM and CVD.

- Statistical modeling of the use and effectiveness of specific cardiac treatments and of changes in risk factors between 1980 and 2000 among US adults 25 to 84 years of age showed that the age-adjusted death rate for CHD decreased from 543 to 267 deaths per 100 000 population among men and from 263 to 134 deaths per 100 000 population among women. Approximately 47% of this decrease was attributed to treatments, and  $\approx 44\%$  was attributed to changes in risk factors, although reductions were offset in part by increases in BMI and the prevalence of DM, which accounted for an increased number of deaths (8% and 10%, respectively).<sup>27</sup> An analysis from the Cooper Clinic in Dallas, TX, of exercise electrocardiographic responses and CVD mortality in 2854 men with DM reported 441 deaths (210 CVD and 133 CHD) over a follow-up of 16 years. That analysis showed that equivocal and abnormal exercise electrocardiographic responses were associated with higher risk of all-cause, CVD, and CHD mortality. Across normal, equivocal, and abnormal exercise electrocardiographic groups, age- and examination year-adjusted CHD mortality rates per 10 000 person-years were 23.0, 48.6, and 69.0, respectively ( $P$  for trend  $< 0.001$ ), and risk factor-adjusted HRs were 1.00, 1.68 (95% CI, 1.01 to 2.77), and 2.21 (95% CI, 1.41 to 3.46;  $P$  for trend  $< 0.001$ ), respectively.<sup>28</sup>
- A subgroup analysis was conducted of patients with DM enrolled in randomized clinical trials that evaluated ACS therapies. The data included 62 036 patients from TIMI studies (46 577 with STEMI and 15 459 with unstable angina/non-STEMI [UA/NSTEMI]). Of these, 17.1% had DM. Modeling showed that mortality at 30 days was significantly higher among patients with DM than among those without DM who presented with UA/NSTEMI (2.1% versus 1.1%;  $P \leq 0.001$ ) and STEMI (8.5% versus 5.4%;  $P = 0.001$ ), with adjusted risks for 30-day mortality in DM versus no DM of 1.78 for UA/NSTEMI (95% CI, 1.24 to 2.56) and 1.40 (95% CI, 1.24 to 1.57) for STEMI. DM was also associated with significantly higher mortality 1 year after UA/NSTEMI or STEMI. By 1 year after ACS, patients with DM presenting with UA/NSTEMI had a risk of death that approached that of patients without DM presenting with STEMI (7.2% versus 8.1%).<sup>29</sup>
- Data from the ARIC study of the NHLBI found that DM was a weaker predictor of CHD in blacks than in whites.<sup>30</sup>
- Data from Framingham, MA, show that despite improvements in CVD morbidity and mortality, DM continues to

elevate CVD risk. Participants 45 to 64 years of age from the FHS original and offspring cohorts who attended examinations in 1950 to 1966 ("earlier" time period) and 1977 to 1995 ("later" time period) were followed up for incident MI, CHD death, and stroke. Among participants with DM, the age- and sex-adjusted CVD incidence rate was 286.4 per 10 000 person-years in the earlier period and 146.9 per 10 000 person-years in the later period, a 35.4% decline. HRs for DM as a predictor of incident CVD were not significantly different in the earlier (risk factor-adjusted HR, 2.68; 95% CI, 1.88 to 3.82) versus later (HR, 1.96; 95% CI, 1.44 to 2.66) periods.<sup>31</sup> Thus, although there was a 50% reduction in the rate of incident CVD events among adults with DM, the absolute risk of CVD remained 2-fold greater than among people without DM.<sup>31</sup>

— Data from these earlier and later time periods in Framingham also suggest that the increasing prevalence of DM is leading to an increasing rate of CVD, resulting in part from CVD risk factors that commonly accompany DM. The age- and sex-adjusted HR for DM as a CVD risk factor was 3.0 in the earlier time period and 2.5 in the later time period. Because the prevalence of DM has increased over time, the population-attributable risk for DM as a CVD risk factor increased from 5.4% in the earlier time period to 8.7% in the later time period (attributable risk ratio, 1.62;  $P=0.04$ ). Adjustment for CVD risk factors (age, sex, hypertension, current smoking, high cholesterol, and obesity) weakened this attributable risk ratio to 1.5 ( $P=0.12$ ).<sup>32</sup>

— Other data from Framingham show that over 30 years, CVD among women with DM was 54.8% among normal-weight women but 78.8% among obese women. Among normal-weight men with DM, the lifetime risk of CVD was 78.6%, whereas it was 86.9% among obese men.<sup>33</sup>

- Other studies show that the increased prevalence of DM is being followed by an increasing prevalence of CVD morbidity and mortality. New York City death certificate data for 1989 to 1991 and 1999 to 2001 and hospital discharge data for 1988 to 2002 show increases in all-cause and cause-specific mortality between 1990 and 2000, as well as in annual hospitalization rates for DM and its complications among patients hospitalized with AMI and/or DM. During this decade, all-cause and cause-specific mortality rates declined, although not for patients with DM; rates increased 61% and 52% for diabetic men and women, respectively, as did hospitalization rates for DM and its complications. The percentage of all AMIs occurring in patients with DM increased from 21% to 36%, and the absolute number more than doubled, from 2951 to 6048. Although hospital days for AMI fell overall, for those with DM, they increased 51% (from 34 188 to 51 566). These data suggest that increases in DM rates threaten the long-established nationwide trend toward reduced coronary artery events.<sup>34</sup>
- In an analysis of provincial health claims data for adults living in Ontario, Canada, between 1992 and 2000, the rate

of patients admitted for AMI and stroke decreased to a greater extent in the diabetic than the nondiabetic population (AMI,  $-15.1\%$  versus  $-9.1\%$ ,  $P=0.0001$ ; stroke,  $-24.2\%$  versus  $-19.4\%$ ,  $P=0.0001$ ). Diabetic patients experienced reductions in case fatality rates related to AMI and stroke similar to those without DM ( $-44.1\%$  versus  $-33.2\%$ ,  $P=0.1$ ;  $-17.1\%$  versus  $-16.6\%$ ,  $P=0.9$ , respectively) and similarly comparable decreases in all-cause mortality. Over the same period, the number of DM cases increased by 165%, which translates to a marked increase in the proportion of CVD events occurring among patients with DM: AMI, 44.6%; stroke, 26.1%; AMI deaths, 17.2%; and stroke deaths, 13.2%.<sup>35</sup>

- In the same data set, the transition to a high-risk category (an event rate equivalent to a 10-year risk of 20% or an event rate equivalent to that associated with previous MI) occurred at a younger age for men and women with DM than for those without DM (mean difference, 14.6 years). For the outcome of AMI, stroke, or death resulting from any cause, diabetic men and women entered the high-risk category at 47.9 and 54.3 years of age, respectively. The data suggest that DM confers a risk equivalent to aging 15 years. In North America, diverse data show lower rates of CVD among diabetic people, but as the prevalence of DM has increased, so has the absolute burden of CVD, especially among middle-aged and older individuals.<sup>36</sup>
- HbA<sub>1c</sub> levels  $\geq 6.5\%$  can be used to diagnose DM.<sup>37</sup> In the population-based ARIC study, HbA<sub>1c</sub> levels  $\geq 6.5\%$  had a 14-year follow-up, multivariable-adjusted HR for diagnosed DM of 16.5 (95% CI, 14.2 to 19.1) and for CHD of 1.95 (95% CI, 1.53 to 2.48) relative to those with HbA<sub>1c</sub>  $< 5.0\%$ .<sup>38</sup>

## Risk Factors

- Data from the 2004 National Healthcare Disparities Report (AHRQ, US Department of Health and Human Services) found that only approximately one third of adults with DM received all 5 interventions to reduce risk factors recommended for comprehensive DM care in 2001. The proportion receiving all 5 interventions was lower among blacks than whites and among Hispanics than non-Hispanic whites.<sup>39</sup>

— In multivariate models that controlled for age, sex, income, education, insurance, and residence location, blacks were 38% less likely and Hispanics were 33% less likely than their respective comparison groups to receive all recommended risk factor interventions in 2001.<sup>39</sup>

- Between NHANES III 1988 to 1994 (NCHS) and NHANES 1999 to 2002 (NCHS), considerable differences were found among ethnic groups in glycemic control rates among adults with type 2 DM. Among non-Hispanic whites, the control rates were 43.8% in 1988 to 1994 and 48.4% in 1999 to 2002. For non-Hispanic blacks, the rates were 41.2% and 36.5%, respectively. For Mexican Americans, the respective rates were 34.5% and 34.2%.<sup>40</sup>

- In 1 large academic medical center, outpatients with type 2 DM were observed during an 18-month period for proportions of patients who had HbA<sub>1c</sub> levels, BP, or total cholesterol levels measured; who had been prescribed any drug therapy if HbA<sub>1c</sub> levels, SBP, or LDL cholesterol levels exceeded recommended treatment goals; and who had been prescribed greater-than-starting-dose therapy if these values were above treatment goals. Patients were less likely to have cholesterol levels measured (76%) than HbA<sub>1c</sub> levels (92%) or BP (99%;  $P<0.0001$  for either comparison). The proportion of patients who received any drug therapy was greater for above-goal HbA<sub>1c</sub> (92%) than for above-goal SBP (78%) or LDL cholesterol (38%;  $P<0.0001$  for each comparison). Similarly, patients whose HbA<sub>1c</sub> levels were above the treatment goal (80%) were more likely to receive greater-than-starting-dose therapy than were those who had above-goal SBP (62%) and LDL cholesterol levels (13%;  $P<0.0001$ ).<sup>41</sup>

— Data from the same academic medical center also showed that CVD risk factors among women with DM were managed less aggressively than among men with DM. Women were less likely than men to have HbA<sub>1c</sub> <7% (without CHD: adjusted OR for women versus men, 0.84,  $P=0.005$ ; with CHD: 0.63,  $P<0.0001$ ). Women without CHD were less likely than men to be treated with lipid-lowering medication (0.82;  $P=0.01$ ) or, when treated, to have LDL cholesterol levels <100 mg/dL (0.75;  $P=0.004$ ) and were less likely than men to be prescribed aspirin (0.63;  $P<0.0001$ ). Women with DM and CHD were less likely than men to be prescribed aspirin (0.70,  $P<0.0001$ ) and, when treated for hypertension or hyperlipidemia, were less likely to have BP levels <130/80 mm Hg (0.75;  $P<0.0001$ ) or LDL cholesterol levels <100 mg/dL (0.80;  $P=0.006$ ).<sup>42</sup>

- In 2001 to 2002, among adults  $\geq 18$  years of age with DM, 50.2% were not at goal for HbA<sub>1c</sub> (<7%), 64.6% were not at goal for LDL cholesterol (<100 mg/dL), and 53% were not at goal for BP (<130/80 mm Hg). Moreover, 48.6% were not at recommended levels of triglycerides (<150 mg/dL in women). Only 5.3% of men and 12.7% of women were simultaneously at goal for HbA<sub>1c</sub>, LDL cholesterol, and BP.<sup>43</sup>
- Analysis of data from the CHS study of the NHLBI found that lifestyle risk factors, including physical activity level, dietary habits, smoking habits, alcohol use, and adiposity measures, assessed late in life, were each independently associated with risk of new-onset DM. Participants whose PA level and dietary, smoking, and alcohol habits were all in the low-risk group had an 82% lower incidence of DM compared with all other participants. When absence of adiposity was added to the other 4 low-risk lifestyle factors, incidence of DM was 89% lower.<sup>44</sup>
- Aggressive treatment of hypertension is recommended for adults with DM to prevent cardiovascular complications. Between NHANES III (1984 to 1992) and NHANES 1999 to 2004, the proportion of patients with DM whose BP was

treated increased from 76.5% to 87.8%, and the proportion whose BP was controlled nearly doubled (15.9% to 29.6%).<sup>45</sup>

## Hospitalizations

### Youth

- National Inpatient Sample data from 1993 to 2004 were analyzed for individuals 0 to 29 years of age with a diagnosis of DM. Rates of hospitalizations increased by 38%. Hospitalization rates were higher for females (42%) than for males (29%). Inflation-adjusted total charges for DM hospitalizations increased 130%, from \$1.05 billion in 1993 to \$2.42 billion in 2004.<sup>46</sup>

### Cost

In 2007, the direct (\$116 billion) and indirect (\$58 billion) cost attributable to DM was \$174 billion.<sup>6</sup> These estimates include not just DM as a primary diagnosis but also DM-related long-term complications that are attributed to DM.<sup>47</sup>

A study of data from NHANES 2003 to 2006, Ingenix Research DataMart, 2003 to 2005 National Ambulatory Medical Care Survey, the 2003 to 2005 National Hospital Ambulatory Medical Care Survey, the 2004 to 2005 Nationwide Inpatient Sample, and the 2003 to 2005 Medical Expenditure Panel Survey found that the estimated economic cost of undiagnosed DM in 2007 was \$18 billion, including medical costs of \$11 billion and indirect costs of \$7 billion.<sup>48</sup>

Ellipses (. . .) indicate data not available; NH indicates non-Hispanic; DM, diabetes mellitus.

Undiagnosed DM is defined as those whose fasting glucose is ≥126 mg/dL but who did not report being told by a healthcare provider that they had DM. Prediabetes is a fasting blood glucose of 100 to <126 mg/dL (impaired fasting glucose). Prediabetes includes impaired glucose tolerance.

\*Mortality data are for whites and blacks and include Hispanics.

†Centers for Disease Control and Prevention; National Diabetes Fact Sheet, 2007. Accessed June 24, 2008.

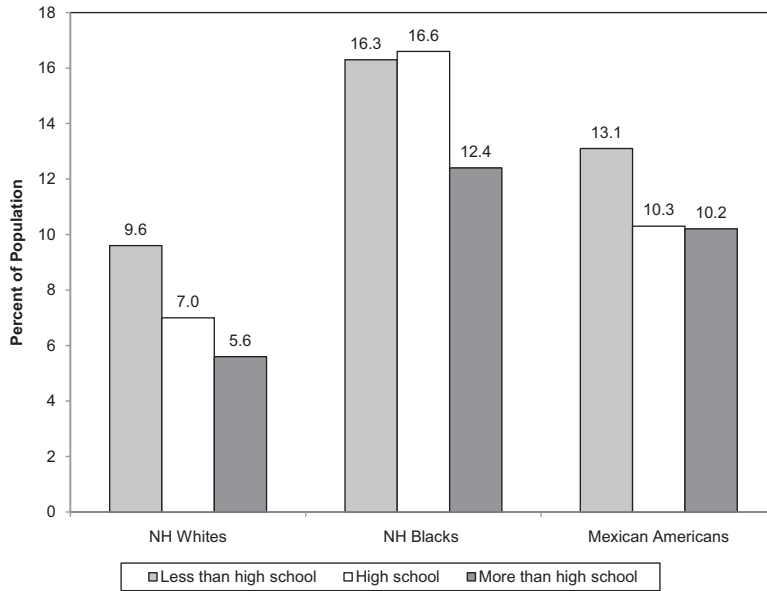

‡These percentages represent the portion of total DM mortality that is for males versus females.

Sources: Prevalence: Prevalence of diagnosed and undiagnosed diabetes: National Health and Nutrition Examination Survey 2005–2008, National Center for Health Statistics, and National Heart, Lung, and Blood Institute. Percentages for racial/ethnic groups are age-adjusted for Americans ≥20 years of age. Age-specific percentages are extrapolations to the 2008 US population estimates. Incidence: National Institute of Diabetes and Digestive and Kidney Diseases estimates. Mortality: National Center for Health Statistics. These data represent underlying cause of death only. Hospital discharges: National Hospital Discharge Survey, National Center for Health Statistics; data include those inpatients discharged alive, dead, or status unknown.

## 17. End-Stage Renal Disease and Chronic Kidney Disease

ICD-10 N18.0. See Tables 17-1 through 17-3.

End-stage renal disease is a condition that is most commonly associated with DM and/or HBP, occurs when the kidneys are functioning at a very low level, and is currently defined as the receipt of chronic renal replacement treatment such as hemodialysis, peritoneal dialysis, or kidney transplantation. The end-stage renal disease (ESRD) population is increasing in size and cost as those with chronic kidney disease (CKD) transition to ESRD and as a result of changing practice patterns in the United States.

- Data from the 2009 annual report of the US Renal Data System (USRDS) showed that in 2007, the prevalence of ESRD was 527 282, with 65% of these prevalent cases being treated with hemodialysis.<sup>1</sup>
- In 2007, 110 996 new cases of ESRD were reported.<sup>1</sup>
- In 2007, mortality rates for those who were receiving dialysis were 6.7 to 8.5 times greater than those of the general US population.<sup>1</sup>
- In 2007, 17 513 kidney transplants were performed.<sup>2</sup>
- Data from a large cohort of insured patients found that in addition to established risk factors for ESRD, lower hemoglobin levels, higher serum uric acid levels, self-reported history of nocturia, and family history of kidney disease are independent risk factors for ESRD.<sup>3</sup>
- Data from a large insured population revealed that among adults with a glomerular filtration rate (GFR) >60

$\text{mL} \cdot \text{min}^{-1} \cdot 1.73 \text{ m}^{-2}$  and no evidence of proteinuria or hematuria at baseline, risks for ESRD increased dramatically with higher baseline BP level, and in this same patient population, BP-associated risks were greater in men than in women and in blacks than in whites<sup>4</sup> (see Table 17-1).

- Compared with white patients with similar levels of kidney function, black patients are much more likely to progress to ESRD and are on average 10 years younger when they reach ESRD.<sup>5,6</sup>
- Results from a large community-based population showed that higher BMI also independently increased the risk of ESRD. The higher risk of ESRD with overweight and obesity was consistent across age, sex, and race and in the presence or absence of DM, hypertension, or known baseline kidney disease<sup>7</sup> (see Table 17-2).

### Age, Sex, Race, and Ethnicity

- The median age of the population with ESRD in 2007 varied across different racial/ethnic groups: 57.1 years for blacks, 57.9 years for Native American, 59.1 years for Asians, and 60.3 years for whites.<sup>1</sup>
- Treatment of ESRD is more common in men than in women.<sup>1</sup>
- Blacks, Hispanics, Asian Americans, and Native Americans have significantly higher rates of ESRD than do white/Europeans. Blacks represent nearly 28% of treated patients with ESRD.<sup>1</sup>

### Chronic Kidney Disease

#### Prevalence

- CKD, defined as reduced GFR and/or excess urinary protein excretion, is a serious health condition and a worldwide public health problem. The incidence and prevalence of CKD are increasing in the United States and are associated with poor outcomes and a high cost to the US healthcare system. Controversy exists about whether CKD itself independently causes incident CVD, but it is clear that people with CKD, as well as those with ESRD, represent a population at very high risk for CVD events. In fact, individuals with CKD are more likely to die of CVD than to transition to ESRD. The USRDS estimates that by 2020, >700 000 Americans will have ESRD, with >500 000 requiring dialysis and >250 000 receiving a transplant.<sup>1</sup>
- The National Kidney Foundation (NKF) Kidney Disease Outcome Quality Initiative (K/DOQI) developed guidelines in 2002 that provided a standardized definition for CKD. Prevalence estimates may differ depending on assumptions used in obtaining estimates, including which equation is used to estimate GFR and methods for measuring proteinuria.<sup>8</sup> The most recent US prevalence estimates of CKD, with the use of K/DOQI guidelines, come from NHANES 1999 to 2004 (NCHS) in adults  $\geq 20$  years of age<sup>9</sup>:

- The prevalence of CKD (stages I to V)<sup>10</sup> is 16.8%.<sup>9</sup> This represents an increase from the 14.5% prevalence estimate from NHANES 1988 to 1994 (NCHS; recalculated).<sup>9</sup>
- The prevalence of GFR  $\geq 90 \text{ mL} \cdot \text{min}^{-1} \cdot 1.73 \text{ m}^{-2}$  with kidney damage (ie, presence of albuminuria) is 5.7%.

#### Abbreviations Used in Chapter 17

ACR	albumin/creatinine ratio
BMI	body mass index
BP	blood pressure
CHD	coronary heart disease
CHF	congestive heart failure
CKD	chronic kidney disease
CVD	cardiovascular disease
DM	diabetes mellitus
eGFR	estimated glomerular filtration rate
ESRD	end-stage renal disease
GFR	glomerular filtration rate
HBP	high blood pressure
HF	heart failure
$\text{kg/m}^2$	kilograms per square meter
K/DOQI	Kidney Disease Outcome Quality Initiative
$\text{mL} \cdot \text{min}^{-1} \cdot 1.73 \text{ m}^{-2}$	first morning urine protein/creatinine ratio
NCHS	National Center for Health Statistics
NHANES	National Health and Nutrition Examination Survey
NHDS	National Hospital Discharge Survey
NKF	National Kidney Foundation
PAD	peripheral arterial disease
RR	relative risk
USRDS	US Renal Data System

- The prevalence of stage II CKD (estimated glomerular filtration rate (eGFR), 60 to 89 mL · min<sup>-1</sup> · 1.73 m<sup>-2</sup> with kidney damage) is 5.4%.
- The prevalence of stage III CKD (eGFR, 30 to 59 mL · min<sup>-1</sup> · 1.73 m<sup>-2</sup>) is 5.4%.
- The prevalence of stages IV and V CKD (eGFR <29 mL · min<sup>-1</sup> · 1.73 m<sup>-2</sup>) is 0.4%.
- Nearly 26 million people (13%) in the United States have CKD, and most are undiagnosed.<sup>11</sup> Another 20 million are at increased risk for CKD.<sup>2</sup>

### Demographics

- Using current definitions, the prevalence of CKD is higher with older age:<sup>1</sup>
  - 5.7% for those 20 to 39 years of age;
  - 5.7% for those 40 to 59 years of age; and
  - 37.8% for those ≥60 years of age.
- CKD prevalence was greater among those with DM (43.7%) and hypertension (28.0%) than among those without these chronic conditions.<sup>1</sup>
- The prevalence of CKD was slightly higher among Mexican Americans (18.7%) and non-Hispanic blacks (19.9%) than among non-Hispanic whites (16.1%). This disparity was most evident for those with stage I CKD; non-Hispanic whites had a CKD prevalence of 4.2% compared with prevalences among Mexican Americans and non-Hispanic blacks of 10.2% and 9.4%, respectively.<sup>9</sup>

### Risk Factors

- Many traditional CVD risk factors are also risk factors for CKD, including older age, male sex, hypertension, DM, smoking, and family history of CVD.
- Other risk factors include systemic conditions such as autoimmune diseases, systemic infections, and drug exposure, as well as anatomically local conditions such as urinary tract infections, urinary stones, lower urinary tract obstruction, and neoplasia. Even after adjustment for these risk factors, excess CVD risk remains.<sup>12</sup>
- Many clinical risk factors for CKD are the same as those for CVD.
- Proteinuria is a strong independent risk factor for a decline in eGFR, regardless of DM status, and is associated with many of the same risk factors for CVD as for CKD.<sup>13,14</sup>

### ESRD/CKD and CVD

- CVD is the leading cause of death among those with ESRD, although the specific cardiovascular cause of death may be more likely to be arrhythmic compared with an acute myocardial infarction, end-stage heart failure, or stroke.
  - CVD mortality is 5 to 30 times higher in dialysis patients than in subjects from the general population of the same age, sex, and race.<sup>15,16</sup>
  - Individuals with less severe forms of kidney disease are also at significantly increased CVD risk independently of typical CVD risk factors.<sup>17</sup>

— CKD is a risk factor for recurrent CVD events.<sup>18</sup>

- Studies from a broad range of cohorts demonstrate an association between reduced eGFR and elevated risk of CVD, CVD outcomes, and all-cause death<sup>17,19–25</sup> that appears to be largely independent of other known major CVD risk factors.
- Any degree of albuminuria, starting below the microalbuminuria cut point, has been shown to be an independent risk factor for cardiovascular events, CHF hospitalization, PAD, and all-cause death in a wide variety of cohorts.<sup>26–31</sup>
  - A recent meta-analysis of 21 published studies of albuminuria involving 105 872 participants (730 577 person-years) from 14 studies with urine albumin/creatinine ratio (ACR) measurements and 1 128 310 participants (4 732 110 person-years) from 7 studies with urine dipstick measurements showed that excess albuminuria or proteinuria is independently associated with a higher risk of CVD and all-cause mortality.<sup>32</sup>
  - People with both albuminuria/proteinuria and reduced eGFR are at particularly high risk for CVD, CVD outcomes, and death.<sup>33</sup>
  - The exact reasons why CKD and ESRD increase the risk of CVD have not been completely delineated but are clearly multifactorial and likely involve pathological alterations in multiple organ systems and pathways.

### Cost—ESRD

- The total annual cost of treating ESRD in the United States was ≈\$24 billion in 2007, representing nearly 6% of the total Medicare budget.<sup>1</sup>
- The total annual cost associated with CKD has not been accurately determined to date.

### Cystatin C: Kidney Function and CVD

Serum cystatin C, another marker of kidney function, has been proposed to be a more sensitive indicator of kidney function than serum creatinine and creatinine-based estimating formulas at higher levels of GFR. It is a low-molecular-weight protein produced at a constant rate by all nucleated cells and appears not to be affected significantly across age, sex, and levels of muscle mass. Cystatin C is excreted by the kidneys, filtered through the glomerulus, and nearly completely reabsorbed by proximal tubular cells.<sup>34</sup> Several equations have been proposed using cystatin C alone and in combination with serum creatinine to estimate kidney function.<sup>35,36</sup>

### All-Cause Mortality

Elevated levels of cystatin C have been shown to be associated with increased risk for all-cause mortality in studies from a broad range of cohorts.<sup>37–39</sup>

### Cardiovascular Disease

- Data from a large national cohort found higher values of cystatin C to be associated with prevalent stroke, angina, and MI,<sup>40</sup> as well as higher BMI.<sup>41</sup>
- Elevated cystatin C was an independent risk factor for HF,<sup>42,43</sup> PAD events,<sup>44</sup> clinical atherosclerosis, and subclin-

ical measures of CVD in older adults,<sup>45</sup> as well as for cardiovascular events among those with CHD.<sup>37,46</sup>

- In several diverse cohorts, elevated cystatin C has been found to be associated with CVD-related mortality,<sup>39,47,48</sup> including sudden cardiac death.<sup>49</sup>

**Table 17-1. Blood Pressure and the Adjusted Risk of End-Stage Renal Disease Among 316 675 Adults Without Evidence of Baseline Kidney Disease**

JNC V BP Category	Adjusted RR (95% CI)
Optimal	1.00 (Reference)
Normal, not optimal	1.62 (1.27–2.07)
High normal	1.98 (1.55–2.52)
Hypertension	
Stage 1	2.59 (2.07–3.25)
Stage 2	3.86 (3.00–4.96)
Stage 3	3.88 (2.82–5.34)
Stage 4	4.25 (2.63–6.86)

JNC V indicates fifth report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure; RR, relative risk; CI, confidence interval.

**Table 17-2. Multivariable Association Between Body Mass Index and Risk of End-Stage Renal Disease Among 320 252 Adults**

BMI, kg/m <sup>2</sup>	Adjusted RR (95% CI)
18.5–24.9 (Normal weight)	1.00 (Reference)
25.0–29.9 (Overweight)	1.87 (1.64–2.14)
30.0–34.9 (Class I obesity)	3.57 (3.05–4.18)
35.0–39.9 (Class II obesity)	6.12 (4.97–7.54)
≥40.0 (Extreme obesity)	7.07 (5.37–9.31)

BMI indicates body mass index; RR, relative risk; CI, confidence interval.

**Table 17-3. Adjusted Hazard Ratio for Death Resulting From Any Cause, Cardiovascular Events, and Hospitalization Among 1 120 295 Ambulatory Adults According to the Estimated Glomerular Filtration Rate\***

Estimated GFR, mL · min <sup>-1</sup> · 1.73 m <sup>-2</sup>	Adjusted Hazard Ratio (95% CI)		
	Death Resulting From Any Cause	Any Cardiovascular Event	Any Hospitalization
≥60†	1.00	1.00	1.00
45–59	1.2 (1.1–1.2)	1.4 (1.4–1.5)	1.1 (1.1–1.1)
30–44	1.8 (1.7–1.9)	2.0 (1.9–2.1)	1.5 (1.5–1.5)
15–29	3.2 (3.1–3.4)	2.8 (2.6–2.9)	2.1 (2.0–2.2)
<15	5.9 (5.4–6.5)	3.4 (3.1–3.8)	3.1 (3.0–3.3)

GFR indicates glomerular filtration rate; CI, confidence interval.

\*The analyses were adjusted for age, sex, income, education, use or nonuse of dialysis, and presence or absence of prior coronary heart disease, prior chronic heart failure, prior ischemic stroke or transient ischemic attack, prior peripheral arterial disease, diabetes mellitus, hypertension, dyslipidemia, a serum albumin level of ≤3.5 g/dL, dementia, cirrhosis or chronic liver disease, chronic lung disease, documented proteinuria, and prior hospitalizations.

†This group served as the reference group.

## 18. Metabolic Syndrome

- Metabolic syndrome refers to a cluster of risk factors for CVD and type 2 DM. Although several different definitions for metabolic syndrome have been proposed, the International Diabetes Federation, NHLBI, AHA, and others recently proposed a harmonized definition for metabolic syndrome.<sup>1</sup> By this definition, metabolic syndrome is diagnosed when  $\geq 3$  of the following 5 risk factors are present:
  - Fasting plasma glucose  $\geq 100$  mg/dL or undergoing drug treatment for elevated glucose.
  - HDL cholesterol  $< 40$  mg/dL in men or  $< 50$  mg/dL in women or undergoing drug treatment for reduced HDL cholesterol.
  - Triglycerides  $\geq 150$  mg/dL or undergoing drug treatment for elevated triglycerides.
  - Waist circumference  $\geq 102$  cm in men or  $\geq 88$  cm in women in the United States.
  - BP  $\geq 130$  mm Hg systolic or  $\geq 85$  mm Hg diastolic or undergoing drug treatment for hypertension or antihypertensive drug treatment in a patient with a history of hypertension.

### Adults

- Prevalence of metabolic syndrome varies by the definition used, with definitions such as the International Diabetes

### Abbreviations Used in Chapter 18

AHA	American Heart Association
ARIC	Atherosclerosis Risk in Communities
aROC	area under the receiver-operating characteristic curve
ATP III	Adult Treatment Panel III
BMI	body mass index
BP	blood pressure
CHD	coronary heart disease
CI	confidence interval
cm	centimeter
CVD	cardiovascular disease
DM	diabetes mellitus
FRS	Framingham Risk Score
HDL	high-density lipoprotein
HR	hazard ratio
HF	heart failure
mg/dL	milligrams per deciliter
mm Hg	millimeters of mercury
NCEP	National Cholesterol Education Program
NCHS	National Center for Health Statistics
NHANES	National Health and Nutrition Examination Survey
NHLBI	National Heart, Lung, and Blood Institute
OR	odds ratio
PA	physical activity
RR	relative risk

- Federation that suggest lower thresholds for defining central obesity resulting in higher prevalence estimates.<sup>2</sup>
- On the basis of NHANES 2003 to 2006 data and National Cholesterol Education Program (NCEP)/ATP III guidelines,  $\approx 34\%$  of adults  $\geq 20$  years of age met the criteria for metabolic syndrome.<sup>3</sup>
- Also based on NHANES 2003 to 2006 data<sup>3</sup>:
  - The age-adjusted prevalence was 35.1% for men and 32.6% for women.
  - Among men, the age-specific prevalence ranged from 20.3% among people 20 to 39 years of age to 40.8% for people 40 to 59 years of age and 51.5% for people  $\geq 60$  years of age. Among women, the age-specific prevalence ranged from 15.6% among people 20 to 39 years of age to 37.2% for people 40 to 59 years of age and 54.4% for those  $\geq 60$  years of age.
  - The age-adjusted prevalences of people with metabolic syndrome were 37.2%, 25.3%, and 33.2% for non-Hispanic white, non-Hispanic black, and Mexican American men, respectively. Among women, the percentages were 31.5%, 38.8%, and 40.6%, respectively.
  - The age-adjusted prevalence was  $\approx 53\%$  higher among non-Hispanic black women than among non-Hispanic black men and  $\approx 22\%$  higher among Mexican American women than among Mexican American men.

- The prevalence of metabolic syndrome is also high among immigrant Asian Indians, ranging between 26.8% and 38.2%, depending on the definition used.<sup>4</sup>
- The prevalence of metabolic syndrome among pregnant women increased to 26.5% during 1999 to 2004 from 17.8% during 1988 to 1994.<sup>5</sup>
- However, the public's recognition of metabolic syndrome is limited.<sup>6</sup>

### Children/Adolescents

- An AHA scientific statement about metabolic syndrome in children and adolescents was released in 2009.<sup>7</sup>
- Metabolic syndrome should be diagnosed with caution in children and adolescents because metabolic syndrome categorization in adolescents is not stable. Approximately half of the 1098 adolescent participants in the Princeton School District Study diagnosed with pediatric ATP III metabolic syndrome lost the diagnosis over 3 years of follow-up.<sup>8</sup>
- Additional evidence of the instability of the diagnosis of metabolic syndrome in children exists. In children 6 to 17 years of age participating in research studies in a single clinical research hospital, the diagnosis of metabolic syndrome was unstable in 46% of cases after a mean of 5.6 years of follow-up.<sup>9</sup>
- On the basis of NHANES 1999 to 2002 data, the prevalence of metabolic syndrome in adolescents 12 to 19 years of age was 9.4%, which represents  $\approx 2.9$  million people. It was 13.2% in boys, 5.3% in girls, 10.7% in whites, 5.2% in blacks, and 11.1% in Mexican Americans.<sup>10</sup>
- In 1999 to 2004,  $\approx 4.5\%$  of US adolescents 12 to 17 years of age had metabolic syndrome according to the definition developed by the International Diabetes Federation.<sup>11</sup> In

2006, this prevalence would have represented  $\approx 1.1$  million adolescents 12 to 17 years of age with metabolic syndrome. It increased from 1.2% among those 12 to 13 years of age to 7.1% among those 14 to 15 years of age and was higher among boys (6.7%) than girls (2.1%). Furthermore, 4.5% of white adolescents, 3.0% of black adolescents, and 7.1% of Mexican American adolescents had metabolic syndrome. The prevalence of metabolic syndrome remained relatively stable during successive 2-year periods: 4.5% for 1999 to 2000, 4.4% to 4.5% for 2001 to 2002, and 3.7% to 3.9% for 2003 to 2004.

- In 1999 to 2002, among overweight or obese adolescents, 44% had metabolic syndrome.<sup>10</sup> In 1988 to 1994, two thirds of all adolescents had at least 1 metabolic abnormality.<sup>12</sup>
- Of 31 participants in the NHLBI Lipid Research Clinics Princeton Prevalence Study and the Princeton Follow-Up Study who had metabolic syndrome at baseline, 21 (68%) had metabolic syndrome 25 years later.<sup>13</sup> After adjustment for age, sex, and race, the baseline status of metabolic syndrome was significantly associated with an increased risk of having metabolic syndrome during adulthood (OR, 6.2; 95% CI, 2.8 to 13.8).
- In the Bogalusa Heart Study, 4 variables (BMI, homeostasis model assessment of insulin resistance, ratio of triglycerides to HDL cholesterol, and mean arterial pressure) considered to be part of the metabolic syndrome clustered together in blacks and whites and in children and adults.<sup>14</sup> The degree of clustering was stronger among adults than children. The clustering of rates of change in the components of the metabolic syndrome in blacks exceeded that in whites.
- Cardiovascular abnormalities are associated with metabolic syndrome in children and adolescents.<sup>15,16</sup>

## Risk

### Adults

- Consistent with 2 earlier meta-analyses, a recent meta-analysis of prospective studies concluded that metabolic syndrome increased the risk of developing CVD (summary RR, 1.78; 95% CI, 1.58 to 2.00).<sup>17</sup> The risk of CVD tended to be higher in women (summary RR, 2.63) than in men (summary RR, 1.98;  $P=0.09$ ). On the basis of results from 3 studies, metabolic syndrome remained a predictor of cardiovascular events after adjustment for the individual components of the syndrome (summary RR, 1.54; 95% CI, 1.32 to 1.79).
- Several studies suggest that the FRS is a better predictor of incident CVD than metabolic syndrome.<sup>18–20</sup> In the San Antonio Heart Study, the area under the receiver-operating characteristic curve (aROC) was 0.816 for the FRS and 0.811 for the FRS plus the metabolic syndrome.<sup>18</sup> Furthermore, the sensitivity for CVD at a fixed specificity was significantly higher for the FRS than for the metabolic syndrome. In ARIC, metabolic syndrome did not improve the risk prediction achieved by the FRS.<sup>19</sup> In the British Regional Heart Study, the aROC for the FRS was 0.73 for incident CHD during 10 years of follow-up, and the aROC

for the number of metabolic syndrome components was 0.63.<sup>20</sup> For CHD events during 20 years of follow-up, the aROCs were 0.68 for the FRS and 0.59 for the number of metabolic syndrome components.

- Estimates of relative risk for CVD generally increase as the number of components of metabolic syndrome increases.<sup>20,21</sup> Compared with men without an abnormal component in the Framingham Offspring Study, the HRs for CVD were 1.48 (95% CI, 0.69 to 3.16) for men with 1 or 2 components and 3.99 (95% CI, 1.89 to 8.41) for men with  $\geq 3$  components.<sup>21</sup> Among women, the HRs were 3.39 (95% CI, 1.31 to 8.81) for 1 or 2 components and 5.95 (95% CI, 2.20 to 16.11) for  $\geq 3$  components. Compared with men without a metabolic abnormality in the British Regional Heart Study, the HRs were 1.74 (95% CI, 1.22 to 2.39) for 1 component, 2.34 (95% CI, 1.65 to 3.32) for 2 components, 2.88 (95% CI, 2.02 to 4.11) for 3 components, and 3.44 (95% CI, 2.35 to 5.03) for 4 or 5 components.<sup>20</sup>
- The cardiovascular risk associated with the metabolic syndrome varies on the basis of the combination of metabolic syndrome components present. Of all possible ways to have 3 metabolic syndrome components, the combination of central obesity, elevated BP, and hyperglycemia had the greatest risk for CVD (HR, 2.36; 95% CI, 1.54 to 3.61) and mortality (HR, 3.09; 95% CI, 1.93 to 4.94) in the Framingham Offspring Study.<sup>22</sup>
- Data from the Aerobics Center Longitudinal Study indicate that risk for CVD mortality is increased in men without DM who have metabolic syndrome (HR, 1.8; 95% CI, 1.5 to 2.0). However, among those with metabolic syndrome, the presence of DM is associated with even greater risk for CVD mortality (HR, 2.1; 95% CI, 1.7 to 2.6).<sup>23</sup>
- Analysis of data from NCHS was used to determine the number of disease-specific deaths attributable to all non-optimal levels of each risk factor exposure by age and sex. The results of the analysis of dietary, lifestyle, and metabolic risk factors show that targeting a handful of risk factors has large potential to reduce mortality in the United States.<sup>24</sup>
- In addition to CVD, the metabolic syndrome has also been associated with incident atrial fibrillation<sup>25</sup> and HF.<sup>26</sup>
- The metabolic syndrome is associated with increased healthcare use and healthcare-related costs among individuals with and without DM. Overall, healthcare costs increase by  $\approx 24\%$  for each additional metabolic syndrome component present.<sup>27</sup>

### Children

- Few prospective pediatric studies have examined the future risk for CVD or DM according to baseline metabolic syndrome status. Data from 771 participants 6 to 19 years of age from the NHLBI's Lipid Research Clinics Princeton Prevalence Study and the Princeton Follow-Up Study showed that the risk of developing CVD was substantially higher among those with metabolic syndrome than among those without this syndrome (OR, 14.6; 95% CI, 4.8 to 45.3) who were followed up for 25 years.<sup>13</sup>
- Another analysis of 814 participants of this cohort showed that those 5 to 19 years of age who had metabolic syndrome

at baseline had an increased risk of having DM 25 to 30 years later compared with those who did not have the syndrome at baseline (OR, 11.5; 95% CI, 2.1 to 63.7).<sup>28</sup>

- Additional data from the Princeton Follow-Up Study, the Fels Longitudinal Study, and the Muscatine Study suggest that the absence of components of the metabolic syndrome in childhood had a high negative predictive value for the development of metabolic syndrome or DM in adulthood.<sup>29</sup>

## Risk Factors

- In prospective or retrospective cohort studies, the following factors have been reported as being directly associated with incident metabolic syndrome, defined by one of the major definitions: age,<sup>28,30–32</sup> low educational attainment,<sup>30,33</sup> low socioeconomic status,<sup>34</sup> smoking,<sup>33–36</sup> low levels of PA,<sup>33–39</sup> low levels of physical fitness,<sup>37,40–42</sup> intake of soft drinks,<sup>43</sup> intake of diet soda,<sup>44</sup> magnesium intake,<sup>45</sup> energy intake,<sup>39</sup> carbohydrate intake,<sup>30,35,46</sup> total fat intake,<sup>30,46</sup> Western dietary pattern,<sup>44</sup> meat intake,<sup>44</sup> intake of fried foods,<sup>44</sup> heavy alcohol consumption,<sup>47</sup> abstinence from alcohol use,<sup>30</sup> parental history of DM,<sup>28</sup> long-term stress at work,<sup>48</sup> pediatric metabolic syndrome,<sup>28</sup> obesity or BMI,<sup>30,31,35,39,49</sup> childhood obesity,<sup>50</sup> waist circumference,<sup>32,46,51–54</sup> intra-abdominal fat,<sup>55</sup> gain in weight or BMI,<sup>30,56</sup> change in weight or BMI,<sup>32,35,57</sup> weight fluctuation,<sup>58</sup> BP,<sup>32,46,53,59</sup> heart rate,<sup>60</sup> homeostasis model assessment,<sup>51,61</sup> fasting insulin,<sup>51</sup> 2-hour insulin,<sup>51</sup> proinsulin,<sup>51</sup> fasting glucose or hyperglycemia,<sup>32,51,53</sup> 2-hour glucose,<sup>51</sup> impaired glucose tolerance,<sup>51</sup> triglycerides,<sup>32,46,49,51–53</sup> low HDL cholesterol,<sup>32,46,50,51,53</sup> oxidized LDL,<sup>61</sup> uric acid,<sup>57,62</sup>  $\gamma$ -glutamyltransferase,<sup>57,63,64</sup> alanine transaminase,<sup>57,63,65,66</sup> plasminogen activator inhibitor-1,<sup>67</sup> aldosterone,<sup>67</sup> leptin,<sup>68</sup> C-reactive protein,<sup>69,70</sup> adipocyte-fatty acid binding protein,<sup>71</sup> and free testosterone index.<sup>72</sup>
- The following factors have been reported as being inversely associated with incident metabolic syndrome, defined by one of the major definitions, in prospective or retrospective cohort studies: muscular strength,<sup>73</sup> change in PA or physical fitness,<sup>35,40</sup> alcohol intake,<sup>33,39</sup> Mediterranean diet,<sup>74</sup> dairy consumption,<sup>44</sup> insulin sensitivity,<sup>51</sup> ratio of aspartate aminotransferase to alanine transaminase,<sup>65</sup> total testosterone,<sup>72,75,76</sup> sex hormone-binding globulin,<sup>72,75,76</sup> and  $\Delta 5$ -desaturase activity.<sup>77</sup>
- Furthermore, men were more likely than women to develop metabolic syndrome,<sup>30,32</sup> and blacks were shown to be less likely to develop metabolic syndrome than whites.<sup>30</sup>

## 19. Nutrition

See Tables 19-1 and 19-2 and Charts 19-1 through 19-3.

This chapter of the update highlights national nutritional intake data, focusing on foods, nutrients, dietary patterns, and other dietary factors that are related to cardiometabolic health. It is intended to examine current intakes, trends and changes in intakes, and estimated effects on disease to support and further stimulate efforts to monitor and improve dietary habits in relation to cardiovascular health.

### Prevalence

#### *Foods and Nutrients: Adults*

See Table 19-1; NHANES 2005 to 2006; personal communication with D. Mozaffarian (December 2008).

#### Abbreviations Used in Chapter 19

apo	apolipoprotein
BMI	body mass index
BP	blood pressure
bpm	beats per minute
BRFSS	Behavioral Risk Factor Surveillance System
Cal/d	calories per day
CHD	coronary heart disease
CI	confidence interval
CVD	cardiovascular disease
DASH	Dietary Approaches to Stop Hypertension
DBP	diastolic blood pressure
DHA	docosahexaenoic acid
DHHS	US Department of Health and Human Services
DM	diabetes mellitus
EPA	eicosapentaenoic acid
g	grams
GISSI	Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto miocardico
HD	heart disease
HDL	high-density lipoprotein
HEI	Healthy Eating Index
HOMA	homeostasis model assessment
kCal	kilocalories
LDL	low-density lipoprotein
mg	milligrams
mg/dL	milligrams per deciliter
mg/L	milligrams per liter
mm Hg	millimeters of mercury
NHANES	National Health and Nutrition Examination Survey
PA	physical activity
pmol	picomoles per liter
RR	relative risk
SBP	systolic blood pressure
SD	standard deviation
USDA	US Department of Agriculture
WHI	Women's Health Initiative

The dietary consumption by US adults of selected foods and nutrients related to cardiometabolic health is detailed in Table 19-1 according to sex and ethnic subgroups:

- Average consumption of whole grains by white and black men and women was between 0.5 and 0.7 servings per day, with only between 3% and 5% of white and black adults consuming  $\geq 3$  servings per day. Average whole grain consumption by Mexican Americans was  $\approx 2$  servings per day, with 22% to 28% consuming  $\geq 3$  servings per day.
- Average fruit consumption ranged from 1.1 to 1.8 servings per day in these sex and ethnic subgroups; 8% to 11% of whites, 6% to 9% of blacks, and 6% to 10% of Mexican Americans consumed  $\geq 4$  servings per day. When 100% fruit juices were included, the number of servings consumed and the proportions of adults consuming  $\geq 4$  servings per day approximately doubled.
- Average vegetable consumption ranged from 1.2 to 2.1 servings per day; 11% to 14% of whites, 5% to 10% of blacks, and 3% to 5% of Mexican Americans consumed  $\geq 5$  servings per day. The inclusion of vegetable juices and sauces generally produced little change in these consumption patterns.
- Average consumption of fish and shellfish was lowest among white women (1.4 servings per week) and highest among black and Mexican American men (1.7 servings per week); between 75% and  $>80\%$  of adults in each sex and ethnic subgroup consumed  $< 2$  servings per week. Approximately 6% of whites, 7% of blacks, and 6% to 7% of Mexican Americans consumed  $\geq 500$  mg/d of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA).
- Average consumption of nuts, legumes, and seeds was  $\approx 2$  servings per week among black women, black men, and white women; 3 servings per week among white men; and 6 and 8 servings per week among Mexican American women and men, respectively. Approximately 18% of whites, 14% to 17% of blacks, and 36% to 46% of Mexican Americans consumed  $\geq 4$  servings per week.
- Average consumption of processed meats was lowest among Mexican American women (1.5 servings per week) and highest among black men (3.7 servings per week). Between 40% (Mexican American women) and 68% (black men) of adults consumed  $\geq 1$  serving per week.
- Average consumption of sugar-sweetened beverages ranged from  $\approx 6$  servings per week among white women to 18 servings per week among Mexican American men. Approximately 51% and 32% of white men and women, 76% and 66% of black men and women, and 78% and 61% of Mexican American men and women, respectively, consumed  $> 36$  oz (4.5 eight-oz servings) per week.
- Average consumption of sweets and bakery desserts ranged from  $\approx 4$  servings per day (Mexican American men) to 8 servings per day (white men). Approximately two thirds of white and black men and women and half of all Mexican American men and women consumed  $> 25$  servings per week.
- Between 33% and 54% of adults in each sex and ethnic subgroup consumed  $< 10\%$  of total calories from saturated

fat, and between 59% and 69% consumed <300 mg of dietary cholesterol per day.

- Only 3% to 7% of whites, 2% to 3% of blacks, and 11% to 12% of Mexican Americans consumed  $\geq 28$  g of dietary fiber per day.
- Only 7% to 13% of whites, 9% to 10% of blacks, and 17% to 24% of Mexican Americans consumed <2.3 g of sodium per day. In 2005, the US Department of Health and Human Services (DHHS) and US Department of Agriculture (USDA) recommended that adults in specific groups, including people with hypertension, all middle-aged and older adults, and all blacks, should consume no more than 1.5 g of sodium per day. Overall in 2005 to 2006, the majority (69.2%) of US adults belonged to 1 or more of these specific groups in whom sodium consumption should be 1.5 g/d.<sup>1</sup>

### **Foods and Nutrients: Children and Teenagers**

See Table 19-2; NHANES 2005 to 2006; personal communication with D. Mozaffarian (December 2008).

The dietary consumption by US children and teenagers of selected foods and nutrients related to cardiometabolic health is detailed in Table 19-2:

- Average whole grain consumption was low, ranging from 0.4 to 0.5 servings per day, with 4% of children in different age and sex subgroups consuming  $\geq 3$  servings per day.
- Average fruit consumption was low: 1.5 and 1.3 servings per day in younger boys and girls (5 to 9 years of age), 1.3 servings per day in adolescent boys and girls (10 to 14 years of age), and 0.8 servings per day in teenage boys and girls (15 to 19 years of age). The proportion consuming  $\geq 4$  servings per day was low and decreased with age: 6% in those 5 to 9 years of age, 6% to 8% in those 10 to 14 years of age, and 3% to 4% in those 15 to 19 years of age. When 100% fruit juices were included, the number of servings consumed approximately doubled or tripled, and proportions consuming  $\geq 4$  servings per day were 18% to 19% of those 5 to 9 years of age, 16% of those 10 to 14 years of age, and 10% to 14% of those 15 to 19 years of age.
- Average vegetable consumption was low, ranging from 0.8 to 0.9 servings per day, with only up to 2% of children in different age and sex subgroups consuming  $\geq 5$  servings per day.
- Average consumption of fish and shellfish was low, ranging between 0.6 and 0.8 servings per week in 5- to 9-year-olds, 0.4 to 1.1 servings per week in 10- to 14-year-olds, and 0.6 to 0.7 servings per week in 15- to 19-year-olds. Among all ages, 15% of children and teenagers consumed  $\geq 2$  servings per week.
- Average consumption of nuts, legumes, and seeds ranged from 1.0 to 1.2 servings per week among 15- to 19-year-olds to 1.4 to 1.7 servings per week at younger ages. Between 9% and 13% of children in different age and sex subgroups consumed  $\geq 4$  servings per week.
- Average consumption of processed meats ranged from 2.1 to 3.4 servings per week; was uniformly higher than the average consumption of nuts, legumes, and seeds; and was up to 6 times higher than the average consumption of fish

and shellfish. Between 42% and 60% of children consumed  $\geq 2$  servings per week.

- Average consumption of sugar-sweetened beverages was higher in boys than in girls and was  $\approx 8$  servings per week in 5- to 9-year-olds, 11 to 14 servings per week in 10- to 14-year-olds, and 15 to 23 servings per week in 15- to 19-year-olds. This was generally considerably higher than the average consumption of whole grains, fruits, vegetables, fish and shellfish, or nuts, legumes, and seeds. Only between 13% (boys 15 to 19 years of age) and 40% (boys and girls 5 to 9 years of age) of children consumed 4.5 servings per week.
- Average consumption of sweets and bakery desserts was  $\approx 10$  servings per week in 5- to 9-year-olds and 10- to 14-year-olds and 6 to 9 servings per week in 15- to 19-year-olds. From 82% (5 to 9 years of age) to 59% (15 to 19 years of age) of youths consumed >2.5 servings per week.
- Average consumption of EPA and DHA was low, ranging from  $\approx 40$  to 80 mg/d in boys and girls at all ages. Only between 0.4% and 2.5% of children and teenagers at all ages consumed  $\geq 500$  mg/d.
- Average consumption of saturated fat was between 11% and 12% of calories, and average consumption of dietary cholesterol was  $\approx 230$  mg/d. Approximately one fifth to one third of children consumed <10% energy from saturated fat, and  $\approx 80\%$  consumed <300 mg of dietary cholesterol per day.
- Average consumption of dietary fiber ranged from 11 to 14 g/d. Less than 2% of children in different age and sex subgroups consumed  $\geq 28$  g/d.
- Average consumption of sodium ranged from 3.0 to 3.4 g/d. Between 6% and 12% of children in different age and sex subgroups consumed <2.3 g/d.

### **Energy Balance**

Energy balance, or consumption of total calories appropriate for needs, is determined by the balance of average calories consumed versus expended, with this balance depending on multiple factors, including calories consumed, PA, body size, age, sex, and underlying basal metabolic rate. Thus, one individual may consume relatively high calories but have negative energy balance (as a result of even greater calories expended), whereas another individual may consume relatively few calories but have positive energy balance (because of low calories expended). Given such variation, the most practical and reasonable method to assess energy balance in populations is to assess changes in weight over time (see the Trends section below).

- Average daily caloric intake in the United States is  $\approx 2500$  calories in adult men and 1800 calories in adult women (Table 19-1). In children and teenagers, average caloric intake is higher in boys than in girls and increases with age in boys (Table 19-2). Trends in energy balance are described below.
- Individual nutritional determinants of positive energy balance (more calories consumed than expended), as determined by adiposity or weight gain, include larger portion sizes,<sup>2,3</sup> higher intake of sugar-sweetened beverages,<sup>4,5</sup> and

greater consumption of fast food and commercially prepared meals.<sup>6–10</sup>

- Each of these dietary factors has multiple influences; for example, preferences for portion size are associated with BMI, socioeconomic status, eating in fast food restaurants, and television watching.<sup>11,12</sup> Portion sizes are larger at fast food restaurants than at home or at other restaurants.<sup>13</sup>
- In 1999 to 2000, 41% of US adults consumed  $\geq 3$  commercially prepared meals per week.<sup>7</sup> Between 1999 and 2004, 53% of Americans consumed an average of 1 to 3 restaurant meals per week, and 23% consumed  $\geq 4$  restaurant meals per week.<sup>14</sup> Spending on food away from home, including restaurant meals, catered foods, and food eaten during out-of-town trips, increased from 26% of average annual food expenditures in 1970% to 42% in 2004.<sup>14</sup>
- Macronutrient composition of the diet such as percent calories from total fat or total carbohydrate does not appear to be strongly associated with energy balance as ascertained by weight gain or loss.<sup>15–17</sup> Preliminary evidence suggests that aspects of dietary quality rather than composition such as extent of processing of carbohydrates consumed,<sup>17</sup> consumption of *trans* fat,<sup>18–20</sup> and energy density<sup>21–23</sup> may be associated with energy imbalance as assessed by changes in adiposity or weight, but such data are still emerging. Randomized controlled trials in obese individuals generally show modestly greater weight loss with low-carbohydrate versus low-fat diets at 6 months, but at 1 year, such differences diminish, and a diet that focuses on dietary quality and whole foods may be most successful.<sup>24–26</sup>
- A comparison of BRFSS data in 1996 and 2003 suggested a shift in self-reported dietary strategies to lose weight, with the proportion focusing on energy restriction increasing from 11.3% to 24.9%, and the proportion focusing on restricting fat consumption decreasing from 41.6% to 29.1%.<sup>27</sup>
- Other individual factors associated with positive energy balance (weight gain) include greater television watching (particularly as related to greater food consumption)<sup>28–33</sup> and lower average sleep duration, particularly among children.<sup>34</sup>
- A 2007 to 2008 national survey of 1082 retail stores in 19 US cities found that energy-dense snack foods/beverages were present in 96% of pharmacies, 94% of gas stations, 22% of furniture stores, 16% of apparel stores, and 29% to 65% of other types of stores.<sup>35</sup>
- Societal and environmental factors independently associated with energy imbalance (weight gain), via either increased caloric consumption or decreased expenditure, include education, income, race/ethnicity, and local conditions such as availability of grocery stores, types of restaurants, safety, parks and open spaces, and walking or biking paths.<sup>36–38</sup> PA is covered in a separate chapter of this update.

### Dietary Patterns

In addition to individual foods and nutrients, overall dietary patterns can be used to assess more global dietary quality. Different dietary patterns have been defined, including the Healthy Eating Index (HEI), Alternative Health Eating Index,

Western versus prudent dietary patterns, Mediterranean dietary pattern, and DASH-type diet.

- In 1999 to 2004, only 19.4% of hypertensive US adults were following a DASH-type diet (based on intake of fiber, magnesium, calcium, sodium, potassium, protein, total fat, saturated fat, and cholesterol). This represented a decrease from 26.7% of hypertensive US adults in 1988 to 1994.<sup>39</sup>
- Among older US adults ( $\geq 60$  years of age) in 1999 to 2002, 72% met guidelines for dietary cholesterol intake, but only between 18% and 32% met guidelines for the HEI food groups (meats, dairy, fruits, vegetables, and grains). On the basis of the HEI score, only 17% of older US adults consumed a good-quality diet. Higher HEI scores were seen in white adults and individuals with greater education; lower HEI scores were seen in black adults and smokers.<sup>40</sup>
- Nearly 75 000 women 38 to 63 years of age in the Nurses' Health Study without a history of CVD or DM were followed up from 1984 to 2004. It was found that a greater adherence to the Mediterranean diet, as reflected by a higher Alternate Mediterranean Diet Score, was associated with a lower risk of incident CHD and stroke in women.<sup>41</sup>

### Dietary Supplements

Use of dietary supplements is common in the United States among both adults and children:

- Half (53%) of US adults in 2001 to 2004 used dietary supplements, with the most common supplement being multivitamins and multiminerals (67% of supplement users). Most supplements were taken daily and for at least 2 years. Supplement use was associated with older age, higher education, greater PA, wine intake, lower BMI, and white race.<sup>14,42</sup>
- One third (32%) of US children (birth to 18 years of age) used dietary supplements in 1999 to 2002, with the highest use (48.5%) occurring among 4- to 8-year-olds. The most common supplements were multivitamins and multiminerals (58% of supplement users). The primary nutrients supplemented (either by multivitamins and/or individual vitamins) included vitamin C (29% of US children), vitamin A (26%), vitamin D (26%), calcium (21%), and iron (19%). Supplement use was associated with higher family income, a smoke-free home environment, lower child BMI, and less screen time (television, video games, or computers).<sup>43</sup>
- In a 2005 to 2006 telephone survey of US adults, 41.3% were making or had made in the past a serious weight-loss attempt. Of these, one third (33.9%) had used a dietary supplement for weight loss, with such use being more common in women (44.9%) than in men (19.8%) and in blacks (48.7%) or Hispanics (41.6%) than in whites (31.2%); in those with high school education or less (38.4%) than in those with some college or more (31.1%); and in those with household income less than \$40 000 per year (41.8%) than in those with higher incomes (30.3%).<sup>44</sup>
- Multiple trials of most dietary supplements, including folate, vitamin C, and vitamin E, have generally shown no significant effect on CVD risk. The major exceptions are long-chain omega-3 fatty acids, for which 3 large random-

ized controlled trials that included populations with and without established HD have shown significant reductions in risk of CVD events at doses of 1 to 2 g/d (Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto miocardico [GISSI]-Prevenzione, Japan EPA Lipid Intervention Study, and GISSI-HF).<sup>45–47</sup> Another multicenter randomized trial conducted in a population with diabetic nephropathy found that B vitamin supplementation containing folic acid (2.5 mg/d), vitamin B<sub>6</sub> (25 mg), and vitamin B<sub>12</sub> (1 mg/d) resulted in a greater decrease in glomerular filtration rate and an increase in myocardial infarction and stroke compared with placebo.<sup>48</sup>

## Trends

### *Energy Balance*

Energy balance, or consumption of total calories appropriate for needs, has been steadily worsening in the United States over the past several decades, as evidenced by the dramatic increases in overweight and obesity among both children and adults across broad cross sections of sex, race/ethnicity, geographic residence, and socioeconomic status.<sup>49,50</sup>

- Although trends in total calories consumed are difficult to quantify exactly because of differing methods of serial national dietary surveys over time, multiple lines of evidence indicate that average total energy consumption has increased by at least 200 kcal/d per person in the past 3 decades.
- Data from NHANES indicate that between 1971 and 2004, average total energy consumption among US adults increased by 22% in women (from 1542 to 1886 kcal/d) and by 10% in men (from 2450 to 2693 kcal/d; Chart 19-1). These increases are supported by data from the Nationwide Food Consumption Survey (1977–1978) and the Continuing Surveys of Food Intake (1989–1998).<sup>13</sup>
- The increases in calories consumed during this time period are attributable primarily to greater average carbohydrate intake, particularly of starches, refined grains, and sugars (see the Foods and Nutrients section below). Other specific changes related to increased caloric intake in the United States include larger portion sizes, greater food quantity and calories per meal, and increased consumption of sugar-sweetened beverages, snacks, commercially prepared (especially fast food) meals, and higher-energy-density foods.<sup>7,13,51–55</sup>
- Between 1977 to 1978 and 1994 to 1996, the average portion sizes for nearly all foods increased at fast food outlets, other restaurants, and home. These included a 33% increase in the average portion of Mexican food (from 408 to 541 calories), a 34% increase in the average portion of cheeseburgers (from 397 to 533 calories), a 36% increase in the average portion of French fries (from 188 to 256 calories), and a 70% increase in the average portion of salty snacks such as crackers, potato chips, pretzels, puffed rice cakes, and popcorn (from 132 to 225 calories).<sup>13</sup>
- Among US children 2 to 7 years of age, an estimated energy imbalance of only 110 to 165 kcal/d (the equivalent of one 12- to 16-oz bottle of soda/cola) was sufficient to

account for the excess weight gain between 1988 to 1994 and 1999 to 2002.<sup>56</sup>

### *Foods and Nutrients*

Several changes in foods and nutrients have occurred over time. Selected changes are highlighted:

#### *Macronutrients*

- Starting in 1977 and continuing until the most recent dietary guidelines revision in 2005, a major focus of US dietary guidelines was reduction of total dietary fat.<sup>55</sup> During this time, average total fat consumption declined as a percent of calories from 36.9% to 33.4% in men and from 36.1% to 33.8% in women (Chart 19-1).
- Dietary guidelines during this time also emphasized carbohydrate consumption (eg, as the base of the Food Guide Pyramid),<sup>57</sup> which increased from 42.4% to 48.2% of calories in men and from 45.4% to 50.6% of calories in women (Chart 19-1). Evaluated as absolute intakes, the increase in total calories consumed during this period was attributable primarily to the greater consumption of carbohydrates, both as foods (starches and grains) and as beverages.<sup>58,59</sup>

#### *Sugar-Sweetened Beverages*

- Between 1965 and 2002, the average percentage of total calories consumed from beverages in the United States increased from 11.8% to 21.0% of energy, which represents an overall absolute increase of 222 cal/d per person.<sup>54</sup> This increase was due largely to increased consumption of sugar-sweetened beverages and alcohol: Average consumption of fruit juices went from 20 to 39 kcal/d; of milk, from 125 to 94 kcal/d; of alcohol, from 26 to 99 kcal/d; of sweetened fruit drinks, from 13 to 38 kcal/d; and of soda/cola, from 35 to 143 kcal/d (Chart 19-2).
- In addition to increased overall consumption, the average portion size of a single sugar-sweetened beverage increased by >50% between 1977 and 1996, from 13.1 to 19.9 fl oz.<sup>13</sup>
- Among children and teenagers (2 to 19 years of age), the largest increases in consumption of sugar-sweetened beverages between 1988 to 1994 and 1999 to 2004 were seen among black and Mexican American youths compared with white youths.<sup>55</sup>

#### *Fruits and Vegetables*

- Between 1994 and 2005, the average consumption of fruits and vegetables declined slightly, from a total of 3.4 to 3.2 servings per day. The proportions of men and women consuming combined fruits and vegetables  $\geq 5$  times per day were low ( $\approx 20\%$  and  $29\%$ , respectively) and did not change during this period.<sup>60</sup>

## Morbidity and Mortality

### *Effects on Cardiovascular Risk Factors*

In randomized controlled trials, dietary habits affect multiple cardiovascular risk factors, including both established risk factors (SBP, DBP, LDL cholesterol levels, HDL cholesterol levels, glucose levels, and obesity/weight gain) and novel risk factors (eg, inflammation, cardiac arrhythmias, endothelial

cell function, triglyceride levels, lipoprotein(a) levels, and heart rate):

- A DASH dietary pattern with low sodium reduced SBP by 7.1 mm Hg in adults without hypertension and by 11.5 mm Hg in adults with hypertension.<sup>61</sup>
- Compared with the low-fat DASH diet, DASH-type diets that increased consumption of either protein or unsaturated fat had similar or greater beneficial effects on CVD risk factors. Compared with a baseline usual diet, each of the DASH-type diets, which included various percentages (27% to 37%) of total fat and focused on whole foods such as fruits, vegetables, whole grains, and fish, as well as potassium and other minerals and low sodium, reduced SBP by 8 to 10 mm Hg, DBP by 4 to 5 mm Hg, and LDL cholesterol by 12 to 14 mg/dL. The diets that had higher levels of protein and unsaturated fat also lowered triglyceride levels by 16 and 9 mg/dL, respectively.<sup>62</sup>
- In a meta-analysis of randomized controlled trials, consumption of 1% of calories from *trans* fat in place of saturated fat, monounsaturated fat, or polyunsaturated fat increased the ratio of total to HDL cholesterol by 0.031, 0.054, and 0.67; increased apolipoprotein (apo) B levels by 3, 10, and 11 mg/L; decreased apoA-1 levels by 7, 5, and 3 mg/L; and increased lipoprotein(a) levels by 3.8, 1.4, and 1.1 mg/L, respectively.<sup>63</sup>
- In meta-analyses of randomized controlled trials, consumption of EPA and DHA for  $\geq 12$  weeks lowered SBP by 2.1 mm Hg<sup>64</sup> and resting heart rate by 2.5 bpm.<sup>65</sup>
- A review of cross-sectional and prospective cohort studies suggests that higher intake of sugar-sweetened beverages is associated with greater visceral fat and higher risk of type 2 DM.<sup>66</sup> In the PREMIER study, a prospective analysis of the 810 participants indicated that a reduction in sugar-sweetened beverages of 1 serving per day was associated with a reduction in SBP of 1.8 mm Hg (95% CI, 1.2 to 2.4) and in DBP of 1.1 mm Hg (95% CI, 0.7 to 1.4).<sup>67</sup>
- In a randomized controlled trial, compared with a low-fat diet, 2 Mediterranean dietary patterns that included either virgin olive oil or mixed nuts lowered SBP by 5.9 and 7.1 mm Hg, plasma glucose by 7.0 and 5.4 mg/dL, fasting insulin by 16.7 and 20.4 pmol/L, the homeostasis model assessment (HOMA) index by 0.9 and 1.1, and the ratio of total to HDL cholesterol by 0.38 and 0.26 and raised HDL cholesterol by 2.9 and 1.6 mg/dL, respectively. The Mediterranean dietary patterns also lowered levels of C-reactive protein, interleukin-6, intercellular adhesion molecule-1, and vascular cell adhesion molecule-1.<sup>68</sup>
- In the WHI randomized clinical trial,  $n=48\ 835$ , reduction of total fat consumption from 37.8% energy (baseline) to 24.3% energy (at 1 year) and 28.8% energy (at 6 years) had no effect on incidence of CHD (RR, 0.98; 95% CI, 0.88 to 1.09), stroke (RR, 1.02; 95% CI, 0.90 to 1.15), or total CVD (RR, 0.98; 95% CI, 0.92 to 1.05) over a mean of 8.1 years.<sup>69</sup> This was consistent with null results of 4 prior randomized clinical trials (see below) and multiple large prospective cohort studies (see below) that indicated little effect of total fat consumption on risk of CVD.<sup>70–79</sup>
- In 3 separate meta-analyses of prospective cohort studies, the largest including 21 studies with up to 2 decades of follow-up, saturated fat consumption overall had no significant association with incidence of CHD, stroke, or total CVD.<sup>80–82</sup> However, in a pooled individual-level analysis of 11 prospective cohort studies, the specific exchange of polyunsaturated fat consumption in place of saturated fat was associated with lower CHD risk, with 13% lower risk for a 5% energy exchange (RR, 0.87; 95% CI, 0.70 to 0.97).<sup>83</sup> These findings are consistent with a meta-analysis of randomized controlled trials in which increased polyunsaturated fat consumption in place of saturated fat reduced CHD risk, with 10% lower risk for a 5% energy exchange (RR, 0.90; 95% CI, 0.83 to 0.97).<sup>84</sup>
- In a pooled analysis of individual-level data from 11 prospective cohort studies in the United States, Europe, and Israel that included 344 696 participants, each 5% energy of carbohydrate consumption in place of saturated fat was associated with a 7% higher risk of CHD (RR 1.07, 95% CI 1.01 to 1.14).<sup>83</sup> Each 5% energy of monounsaturated fat consumption in place of saturated fat was not significantly associated with CHD risk.<sup>83</sup>
- In a meta-analysis of prospective cohort studies, each 2% of calories from *trans* fat was associated with a 23% higher risk of CHD (RR, 1.23; 95% CI, 1.11 to 1.37).<sup>85</sup>
- In meta-analyses of prospective cohort studies, each daily serving of fruits or vegetables was associated with a 4% lower risk of CHD (RR, 0.96; 95% CI, 0.93 to 0.99) and a 5% lower risk of stroke (RR, 0.95; 95% CI, 0.92 to 0.97).<sup>86,87</sup>
- In a meta-analysis of prospective cohort studies, greater whole grain intake (2.5 compared with 0.2 servings per day) was associated with a 21% lower risk of CVD events (RR, 0.79; 95% CI, 0.73 to 0.85), with similar estimates for specific CVD outcomes (HD, stroke, fatal CVD) and in sex-specific analyses. In contrast, refined grain intake was not associated with lower risk of CVD (RR, 1.07; 95% CI, 0.94 to 1.22).<sup>88</sup>
- In a meta-analysis of 16 prospective cohort studies including 326 572 generally healthy individuals in Europe, the United States, China, and Japan, fish consumption was associated with significantly lower risk of CHD mortality.<sup>89</sup> Compared with no consumption, an estimated 250 mg/d of long-chain omega-3 fatty acids was associated with 35% lower risk of CHD death ( $P<0.001$ ).
- Higher estimated consumption of dietary sodium was not associated with lower CVD mortality in NHANES,<sup>90</sup> although such findings may be limited by changes in behaviors that result from underlying risk (reverse causation). In a posthoc analysis of the Trials of Hypertension Preven-

### Effects on Cardiovascular Outcomes

Because dietary habits affect a broad range of established and novel risk factors, estimation of the impact of nutritional factors on cardiovascular health by considering only a limited number of pathways (eg, only effects on lipids, BP, and obesity) will systematically underestimate or even misconstrue the actual total impact on health. Randomized controlled trials and prospective observational studies can better quantify the total effects of dietary habits on clinical outcomes:

tion, participants randomized to low-sodium interventions had a 25% lower risk of CVD (RR, 0.75; 95% CI, 0.57 to 0.99) after 10 to 15 years of follow-up after the original trials.<sup>91</sup>

- Among 88 520 generally healthy women in the Nurses' Health Study who were 34 to 59 years of age in 1980 and were followed up from 1980 to 2004, regular consumption of sugar-sweetened beverages was independently associated with higher incidence of CHD, with 23% and 35% higher risk with 1 and  $\geq 2$  servings per day, respectively, compared with  $< 1$  per month.<sup>92</sup> Among the 15 745 participants in Atherosclerosis Risk in Communities Study, the odds ratio for developing chronic kidney disease was 2.59 for participants who had a serum uric acid level  $> 9.0$  mg/dL and who drank  $> 1$  sugar-sweetened soda per day.<sup>93</sup>
- In a cohort of 380 296 US men and women, greater versus lower adherence to a Mediterranean dietary pattern, characterized by higher intakes of vegetables, legumes, nuts, fruits, whole grains, fish, and unsaturated fat and lower intakes of red and processed meat, was associated with a 22% lower cardiovascular mortality (RR, 0.78; 95% CI, 0.69 to 0.87).<sup>94</sup> In a cohort of 72 113 US female nurses, a dietary pattern characterized by higher intakes of vegetables, fruits, legumes, fish, poultry, and whole grains was associated with a 28% lower cardiovascular mortality (RR, 0.72; 95% CI, 0.60 to 0.87), whereas a dietary pattern characterized by higher intakes of processed meat, red meat, refined grains, French fries, and sweets/desserts was associated with a 22% higher cardiovascular mortality (RR, 1.22; 95% CI, 1.01 to 1.48).<sup>95</sup> Similar findings have been seen in other cohorts and for other outcomes, including development of DM and metabolic syndrome.<sup>96–100</sup>
- In one report that used consistent and comparable risk assessment methods and nationally representative data, the mortality effects in the United States of 12 modifiable dietary, lifestyle, and metabolic risk factors were assessed. High dietary salt consumption was estimated to be responsible for 102 000 annual deaths, low dietary omega-3 fatty acids for 84 000 annual deaths, high dietary *trans* fatty acids for 82 000 annual deaths, and low consumption of fruits and vegetables for 55 000 annual deaths.<sup>101</sup>

### Cost

The USDA forecast that the Consumer Price Index for all food would increase 4.5% to 5.5% in 2008 as retailers continued to pass on higher commodity and energy costs to consumers in the form of higher retail prices. The Consumer Price Index for food increased 4.0% in 2007, the highest annual increase since 1990. Prices for foods eaten at home increased 4.2% in 2007, whereas prices for foods eaten away from home increased by 3.6%.<sup>55</sup>

- The proportion of total US food expenditures for meals outside the home, as a share of total food dollars, increased from 25% in 1957 to 38% in 1977 to 49% in 2007<sup>57</sup> (Chart 19-3).
- The proportion of sales of meals and snacks from fast food restaurants compared with total meals and snacks away

from home increased from 5% in 1958 to 28% in 1977 to 37% in 2007.<sup>102</sup>

- As a proportion of income, food has become less expensive over time in the United States. As a share of personal disposable income, average (mean) total food expenditures by families and individuals have decreased from 23.5% (1947) to 18.4% (1957) to 13.4% (1977) to 9.8% (2007). For any given year, the share of disposable income spent on food is inversely proportional to absolute income; the share increases as absolute income levels decline.<sup>102</sup>
- Among 154 forms of fruits and vegetables priced with ACNielsen Homescan data, more than half were estimated to cost 25 cents per serving. Consumers could meet a recommendation of 3 servings of fruits and 4 servings of vegetables daily for a total cost of 64 cents per day.<sup>102</sup>
- An overview of the costs of various strategies for primary prevention of CVD determined that the estimated costs per year of life gained were between \$9800 and \$18 000 for statin therapy, \$1500 or more for nurse screening and lifestyle advice, \$500 to \$1250 for smoking cessation, and \$20 to \$900 for population-based healthy eating.<sup>103</sup>
- Each year, more than \$33 billion in medical costs and \$9 billion in lost productivity resulting from HD, cancer, stroke, and DM are attributed to poor nutrition.<sup>104–109</sup>

NH indicates non-Hispanic; EPA, eicosapentaenoic acid; DHA docosahexaenoic acid; ALA,  $\alpha$ -linoleic acid; n-6 PUFA, omega-6 polyunsaturated fatty acid; NA, not available.

Based on data from National Health and Nutrition Examination Survey 2005 to 2006 (two 24-hour dietary recalls per person, with SDs adjusted for within- and between-person variation). All values are energy adjusted, and for comparability, means and proportions are reported for a 2000-kcal/d diet. To obtain actual mean consumption levels, multiply group means by group-specific total caloric consumption divided by 2000.

\*Guidelines adjusted to a 2000-kcal/d diet. Whole grains (characterized as minimum 1.1 g fiber per 10 g carbohydrate), 3 or more 1-oz equivalent (1 oz bread; 1 cup dry cereal; 1/2 cup cooked rice, pasta, or cereal) servings per day (Dietary Guidelines for Americans); fish or shellfish, 2 or more 100-g (3.5-oz) servings per week<sup>106</sup>; fruits, 4 or more 1/2-cup servings per day<sup>108</sup>; vegetables, 5 or more 1/2-cup servings per day, including up to 3 cups per week of starchy vegetables<sup>107</sup>; nuts, legumes, and seeds, 4 or more 50-g servings per week<sup>106</sup>; processed meats (bacon, hot dogs, sausage, processed deli meats), 2 or fewer 100-g (3.5-oz) servings per week (1/4 of discretionary calories)<sup>107</sup>; sugar-sweetened beverages (defined as  $\geq 50$  cal/8 oz, excluding whole juices), 36 oz or less per week ( $\approx 1/4$  of discretionary calories)<sup>106,107</sup>; sweets and bakery desserts, 2.5 or fewer 50-g servings per week ( $\approx 1/4$  of discretionary calories)<sup>106,107</sup>; EPA DHA,  $\geq 0.5$  g/d<sup>108</sup>; ALA,  $\geq 1.6/1.1$  g/d (men/women)<sup>109</sup>; saturated fat,  $<10\%$  energy<sup>107</sup>; dietary cholesterol,  $<300$  mg/d<sup>107</sup>; total fat, 20% to 35% energy<sup>107</sup>; dietary fiber,  $\geq 28$ /d<sup>107</sup>; and sodium,  $<2.3$  g/d.<sup>107</sup>

EPA indicates eicosapentaenoic acid; DHA docosahexaenoic acid; ALA,  $\alpha$ -linoleic acid; n-6 PUFA, omega-6 polyunsaturated fatty acid; NA, not available.

Based on data from National Health and Nutrition Examination Survey 2005 to 2006 (two 24-hour dietary recalls per person, with SDs adjusted for within- and between-person variation). All values are energy adjusted, and for comparability, means and proportions are reported for a 2000-kcal/d diet. To obtain actual mean consumption levels, multiply group means by group-specific total caloric consumption divided by 2000. Each of these guidelines is age-appropriately adjusted to a 2000-kcal/d diet, as for adults.

\*See Table 19-1 for food group, serving size, and guideline definitions.

**Chart 19-1.** Age-adjusted trends in macronutrients and total calories consumed by US adults (20 to 74 years of age), 1971–2004. Data derived from National Center for Health Statistics. *Health, United States 2007, With Chartbook on Trends in the Health of Americans*.<sup>14</sup>

**Chart 19-2.** Per-capita calories consumed from different beverages by US adults ( $\geq 19$  years of age), 1965–2002. Data derived from Nationwide Food Consumption Surveys (1965, 1977–1978), National Health and Nutrition Examination Survey (1988–1994, 1999–2002), and Duffey and Popkin.<sup>54</sup>

**Chart 19-3.** Total US food expenditures away from home and at home, 1977 and 2007. Data derived from US Department of Agriculture Economic Research Service.<sup>57</sup>

## 20. Quality of Care

See Tables 20-1 through 20-11.

The Institute of Medicine (IOM) defines quality of care as “the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge.”<sup>1</sup> The IOM has defined 6 specific domains for improving health care, including care that is safe, effective, patient-centered, timely, efficient, and equitable.

In the following sections, data on quality of care will be presented based on the 6 domains of quality as defined by the IOM. This is intended to highlight current care and to stimulate efforts to improve the quality of cardiovascular care nationally. Where possible, data are reported from recently published literature or standardized quality indicators from quality improvement registries (ie, those consistent with the methods for quality performance measures endorsed by the ACC and the AHA).<sup>2</sup> Additional data on aspects of quality of

### Abbreviations Used in Chapter 20

ACC	American College of Cardiology
ACEI	angiotensin-converting enzyme inhibitor
ACS	acute coronary syndrome
AHA	American Heart Association
AMI	acute myocardial infarction
ARB	angiotensin receptor blocker
BP	blood pressure
CAD	coronary artery disease
CCU	cardiac care unit
CI	confidence interval
COURAGE	Clinical Outcomes Utilizing Revascularization and Aggressive drug Evaluation trial
CPR	cardiopulmonary resuscitation
CRUSADE	Can Rapid Risk Stratification of Unstable Angina Patients Suppress Adverse Outcomes With Early Implementation of the ACC/AHA Guidelines
D2B	door-to-balloon
ED	emergency department
GWTG	Get With The Guidelines
HF	heart failure
ICD	implantable cardioverter-defibrillator
ICU	intensive care unit
IOM	Institute of Medicine
NHANES	National Health and Nutrition Examination Survey
NQF	National Quality Forum
NRCPR	National Registry of Cardiopulmonary Resuscitation
NSTEMI	non-ST-elevation myocardial infarction
OR	odds ratio
PCI	percutaneous coronary intervention
RR	relative risk
SCD-HeFT	Sudden Cardiac Death in Heart Failure Trial
STEMI	ST-elevation myocardial infarction
VHA	Veterans Health Administration

care, such as adherence to ACC/AHA clinical practice guidelines, are also included to provide a spectrum of quality-of-care data. The data selected are meant to provide examples of the current quality of care as reflected by the IOM domain and are not meant to be comprehensive given the sheer number of publications yearly.

- The *safety domain* has been defined as avoiding injuries to patients from the care that is intended to help them. The following are several publications that have focused on safety issues:
  - In a small, single-center study conducted over a 2-month period in the cardiac care unit (CCU) of a tertiary center, Rahim et al<sup>1</sup> demonstrated that iatrogenic adverse events were common (99 of 194 patients), of which bleeding (27%) was the most common preventable iatrogenic adverse event.
  - Using the National Cardiovascular Data Registry CathPCI registry, Tsai et al<sup>2</sup> found that almost one fourth of dialysis patients undergoing PCI (n=22 778) received a contraindicated antithrombotic agent, specifically enoxaparin, eptifibatide, or both. Patients who received a contraindicated antithrombotic agent had an increased risk of in-hospital bleeding (OR 1.63, 95% CI 1.35 to 1.98) and a trend toward increased mortality (OR 1.15, 95% CI 0.97 to 1.36).<sup>2</sup>
  - In a random sample of medical and surgical long-term care adult patients in Massachusetts hospitals, López et al<sup>3</sup> assessed the association between disclosure of an adverse event and patients’ perception of quality of care. Overall, only 40% of adverse events were disclosed. Higher quality ratings were associated with disclosure of an adverse event. Conversely, lower patient perception of quality of care was associated with events that were preventable and with events that caused discomfort.<sup>3</sup>
  - The AHA published a scientific statement<sup>4</sup> about medication errors in acute cardiovascular and stroke patients and classified medication errors into the following categories:
    - Improper dosing or timing, or delivery of an incorrect or unnecessary medication.
    - Administration to the wrong patient (errors of omission).
    - Failure to prescribe appropriate medication therapy or needed monitoring of medication therapy (errors of omission).
  - The following recommendations were made to improve medication safety in long-term cardiovascular care:
    - An accurate patient weight should be obtained on admission.
    - Estimated creatinine clearance should be calculated with the Cockcroft-Gault formula on admission and as changes in creatinine occur.
    - Medication dosage adjustments and heightened surveillance for adverse medication events are recommended owing to age-related changes in pharmacodynamics, pharmacokinetics, and renal function.

- Order forms and protocols for anticoagulation should be standardized.
  - Pharmacists and nurses should be integrated within the cardiovascular care teams in the ED, intensive care unit (ICU), CCU, and inpatient wards to enhance communication and medication safety.
  - Computerized order entry, medication bar-coding technology, and smart infusion pumps should be implemented throughout all inpatient wards, including the ED.
  - Staff should be educated about high-alert medication, safe medication administration techniques, medication reconciliation procedures, and automated dispensing-device technologies.
  - An organizational culture of safety should be cultivated that promotes no-fault internal and external medication error reporting and an interdisciplinary quality improvement review process to reduce the frequency and impact of medication errors.<sup>4</sup>
- *Effective care* has been defined as providing services based on scientific knowledge to all who could benefit and refraining from providing services to those not likely to benefit. There are many quality improvement registries that have been developed for inpatient cardiovascular/stroke care, and the data on these are provided in subsequent tables. Similar efforts are under way for quality-of-care registries in the outpatient setting.
    - In the CRUSADE registry, >7% of patients with STEMI without a reperfusion contraindication did not have reperfusion therapy administered, and this was associated with greater in-hospital mortality. One in 10 patients (10.3%) had a documented contraindication to reperfusion. Primary reasons for contraindications were identified as absence of an ischemic indication (53.8%), bleeding risk (16.7%), patient-related reasons (25.3%), and other (4.2%).<sup>5</sup>
    - According to data from NHANES 1988–1994 and 1999–2008, rates of hypertension have increased from 23.9% in 1988–1994 to 29.0% between 2007 and 2008, and hypertension control has increased from 27.3% in 1988–1994 to 50.1% in 2007–2008. In addition, among patients with hypertension, BP has decreased from 143.0/80.4 to 135.2/74.1 mm Hg.<sup>6</sup>
    - The National Quality Forum (NQF) is a nonprofit organization that aims to improve the quality of health-care for all Americans through fulfillment of its 3-part mission: (1) Setting national priorities and goals for performance improvement; (2) endorsing national consensus standards for measuring and publicly reporting on performance; and (3) promoting the attainment of national goals through education and outreach programs. Recognizing that adherence can impact the effectiveness of therapies, NQF has adopted several performance measures related to medication adherence/persistence, including angiotensin-converting enzyme inhibitor (ACEI)/ angiotensin receptor blocker (ARB) use and persistence among patients with CAD who are at high risk for coronary events, persistence of  $\beta$ -blocker treatment after a heart attack for patients with AMI, and adherence to lipid-lowering medication.<sup>7</sup>
    - Inpatient ACS, HF, and stroke quality-of-care measures data, including trends in care data, where available from national registries, are given in Tables 20-1 to 20-6.
    - Selected outpatient quality-of-care measures from the National Committee for Quality Assurance for 2009 appear in Table 20-7.
  - *Patient-centered care* has been defined as the provision of care that is respectful of and responsive to individual patient preferences, needs, and values and that ensures that patient values guide all clinical decisions. Dimensions of patient-centered care include the following: (1) Respect for patients' values, preferences, and expressed needs; (2) coordination and integration of care; (3) information, communication, and education; (4) physical comfort; (5) emotional support; and (6) involvement of family and friends. Studies focusing on some of these aspects of patient-centered care are highlighted below:
    - The Clinical Outcomes Utilizing Revascularization and AGgressive drug Evaluation (COURAGE) trial,<sup>8</sup> which investigated a strategy of PCI plus optimal medical therapy versus optimal medical therapy alone, demonstrated that both groups had significant improvement in health status during follow-up. By 3 months, health status scores had increased in the PCI group compared with the medical therapy group to 76±24 versus 72±23 for physical limitation ( $P=0.004$ ), 77±28 versus 73±27 for angina stability ( $P=0.002$ ), 85±22 versus 80±23 for angina frequency ( $P<0.001$ ), 92±12 versus 90±14 for treatment satisfaction ( $P<0.001$ ), and 73±22 versus 68±23 for quality of life ( $P<0.001$ ). The PCI plus optimal medical therapy group had a small but significant incremental benefit compared with the optimal medical therapy group early on, but this benefit disappeared by 36 months.
    - In the Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT) <sup>9</sup> of single-lead ICD versus amiodarone for moderately symptomatic HF, patients with ICDs had improvement in quality of life compared with medical therapy patients at 3 and 12 months but not at 30 months. ICD shocks in the month preceding a scheduled assessment were associated with a decrease in quality of life in multiple domains. The authors concluded that the presence of a single-lead ICD was not associated with any detectably adverse quality of life during 30 months of follow-up.
    - Peikes et al<sup>10</sup> reported on 15 care-coordination programs as a part of a Medicare demonstration project for patients with coronary HF, CAD, and DM. Thirteen of the 15 programs did not show a difference in hospitalization rates, and none of the programs demonstrated a net savings. The interventions tested varied significantly, but the majority of the interventions included patient education to improve adherence to medication, diet, exercise, and self-care regimens and improving care coordination through various approaches. These

programs overall had favorable effects on none of the adherence measures and only a few of the many quality-of-care indicators examined. The authors concluded that programs with substantial in-person contact that target moderately to severely ill patients can be cost-neutral and improve some aspects of care.

- Hernandez et al<sup>11</sup> showed that patients with outpatient follow-up within 7 days of discharge for an HF hospitalization were less likely to be readmitted within 30 days in the Get With The Guidelines (GWTG)-HF registry of patients who were  $\geq 65$  years of age. The median length of stay was 4 days (interquartile range, 2 to 6 days), and 21.3% of patients were readmitted within 30 days. At the hospital level, the median percentage of patients who had early follow-up after discharge from the index hospitalization was 38.3% (interquartile range, 32.4% to 44.5%).
- Smolderen et al<sup>12</sup> assessed whether health insurance status affects decisions to seek care for AMI. Uninsured and insured patients with financial concerns were more likely to delay seeking care during AMI and had prehospital delays of more than 6 hours (48.6% of uninsured patients and 44.6% of insured patients with financial concerns compared with only 39.3% of insured patients without financial concerns). Lack of health insurance and financial concerns about accessing care among those with health insurance were each associated with delays in seeking emergency care for AMI.
- Using a cohort (n=192) nested within a randomized trial at a university-affiliated ambulatory practice, Murray et al<sup>13</sup> demonstrated that refill adherence of  $<40\%$  was associated with a 3-fold higher incidence of hospitalization for HF than a refill adherence of  $\geq 80\%$  ( $P=0.002$ ). In multivariable analysis, prescription label-reading skills were associated with a lower incidence of HF-specific emergency care (incidence rate ratio 0.76, 95% CI, 0.19 to 0.69), and participants with adequate health literacy had a lower risk of hospitalization for HF (incidence rate ratio 0.34, 95% CI, 0.15 to 0.76).
- The *timely care* domain relates to reducing waits and sometimes harmful delays for both those who receive and those who give care. Timeliness is an important characteristic of any service and is a legitimate and valued focus of improvement in healthcare and other industries.
  - Chan et al<sup>14</sup> demonstrated significant variation in timely defibrillation ( $<2$  minutes) for in-hospital cardiac arrest among 200 hospitals participating in the National Registry of Cardiopulmonary Resuscitation (NRCPR). Adjusted rates of delayed defibrillation varied from 2.4% to 50.9% of in-hospital cardiac arrests. The variations in defibrillation rates were largely unexplained by traditional hospital factors.
  - Bradley et al<sup>15</sup> demonstrated that participation in the Door-to-Balloon (D2B) Alliance led to a reduction in D2B time to within 90 minutes for patients with STEMI. By March 2008,  $>75\%$  of patients had D2B times of  $\leq 90$  minutes compared with only approximately one fourth of patients in April 2005.
  - From data submitted to GWTG-Resuscitation in 2009:
    - Among children who experienced in-hospital cardiac arrests with an initial shockable rhythm, 74% received a defibrillation attempt within 3 minutes.
    - Among adults in similar situations, 80% received a defibrillation attempt within 3 minutes.
  - Thirty-one percent of adults treated for out-of-hospital cardiac arrest received bystander CPR.<sup>16</sup>
  - Data on time to reperfusion for STEMI or ischemic stroke are provided from national registries in Table 20-8.
- *Efficiency* has been defined as avoiding waste, in particular waste of equipment, supplies, ideas, and energy. In an efficient healthcare system, resources are used to get the best value for the money spent.
  - The AHA and ACC have jointly developed a scientific statement that outlines standards for measures to be used for public reporting of efficiency in health care. The group identified 4 standards important to the development of any efficiency performance measure, including (1) integration of quality and cost, (2) valid cost measurement and analysis, (3) no or minimal incentive to provide poor-quality care, and (4) no or proper attribution of the measure. In the statement, 4 examples were provided of hospital-based efficiency measures, as well as information on how each of the measures fared within the 4 domains recommended. The examples were length of stay, 30-day readmission, hospitalization costs, and nonrecommended imaging tests.
  - At an urban, tertiary-care, academic medical center ED, elements of departmental work flow were redesigned to streamline patient throughput before implementation of a fully integrated ED information system with patient tracking, computerized charting and order entry, and direct access to patient historical data from the hospital data repository. Increasing the clinical information available at the bedside and improving departmental work flow through ED information system implementation and process redesign led to decreased patient throughput times and improved ED efficiency (eg, the length of stay for all patients [from arrival to time patient left ED] decreased by 1.94 hours, from 6.69 [n=508] before the intervention to 4.75 [n=691] after the intervention;  $P<0.001$ ).<sup>17</sup>
  - Himmelstein et al<sup>18</sup> analyzed whether more-computerized hospitals had lower costs of care or administration or better quality to address a common belief that computerization improves healthcare quality, reduces costs, and increases administrative efficiency. They found that hospitals that increased computerization faster had more rapid administrative cost increases ( $P=0.0001$ ); however, higher overall computerization scores correlated weakly with better quality scores for AMI ( $r=0.07$ ,  $P=0.003$ ) but not for HF, pneumonia, or the 3 conditions combined. In multivariate analyses, more-computerized hospitals had

slightly better quality. The authors concluded that hospital computing might modestly improve process measures of quality but does not reduce administrative or overall costs.

- **Equitable care** means the provision of care that does not vary in quality because of personal characteristics such as sex, ethnicity, geographic location, and socioeconomic status. The aim of equity is to secure the benefits of quality health care for all the people of the United States. With regard to equity in caregiving, all individuals rightly expect to be treated fairly by local institutions, including healthcare organizations.

- Chan et al<sup>19</sup> demonstrated that rates of survival to discharge were lower for black patients (25.2%) than for white patients (37.4%). Lower rates of survival to discharge for blacks reflected lower rates of both successful resuscitation (55.8% versus 67.4%) and postresuscitation survival (45.2% versus 55.5%). Adjustment for the hospital site at which patients received care explained a substantial portion of the racial differences in successful resuscitation (adjusted RR 0.92; 95% CI, 0.88 to 0.96;  $P < 0.001$ ) and eliminated the racial differences in postresuscitation survival (adjusted RR 0.99; 95% CI, 0.92 to 1.06;  $P = 0.68$ ). The authors concluded that much of the racial difference was associated with the hospital center in which black patients received care.
- Cohen et al<sup>20</sup> demonstrated that among hospitals engaged in a national quality monitoring and improvement program, evidence-based care for AMI appeared to improve over time for patients irrespective of race/ethnicity, and differences in care by race/ethnicity care were reduced or eliminated. They analyzed 142 593 patients with AMI (121 528 whites, 10 882 blacks, and 10 183 Hispanics) at 443 hospitals participating in the GWTG-CAD program. Overall, defect-free care was 80.9% for whites, 79.5% for Hispanics (adjusted OR versus whites 1.00; 95% CI, 0.94 to 1.06;  $P = 0.94$ ), and 77.7% for blacks (adjusted OR versus whites 0.93; 95% CI, 0.87 to 0.98;  $P = 0.01$ ). A significant gap in defect-free care was observed for blacks during the first half of the study but was no longer present during the remainder of the study. Overall, progressive improvements in defect-free care were observed regardless of race/ethnic groups.
- According to NHANES 1999 to 2006, 45% of adults had at least 1 of 3 chronic conditions (hypertension, hypercholesterolemia, or DM), 13% had 2 of these conditions, and 3% of adults had all 3 conditions. Non-Hispanic black people were more likely than non-Hispanic white and Mexican-American people to have at least 1 of the 3 conditions. In 15% of US adults, 1 or more of the 3 conditions is undiagnosed.<sup>21</sup>
- GWTG data by race, sex, and ethnicity are provided in Tables 20-9 through 20-11.

**Table 20-1. Acute Coronary Syndrome Quality-of-Care Measures, 2009**

Quality-of-Care Measure	VHA*	National Medicare and Medicaid†	AHA GWTG-CAD‡	ACTION/GWTG-STEMI§	ACTION/GWTG-NSTEMI§
Aspirin within 24 h of admission	99	98	91	99	97
Aspirin at discharge	99	98	96	99	97
$\beta$ -blockers within 24 h of admission among AMI and angina patients	97	95	NM	NM	NM
$\beta$ -blockers at discharge	99	98	95	97	95
Lipid-lowering medication at discharge	92	NM	87	98	97
Lipid therapy at discharge if LDL >100 mg/dL	97¶	NM	93	NM	NM
ARB/ACEI at discharge for patients with LVEF <40%	96	95	92	88	84
ACEI at discharge for AMI patients	75	NM	66	NM	NM
Adult smoking cessation advice/counseling	99	99	98	98	97
Cardiac rehabilitation referral for AMI patients	NM	NM	49	84	74

VHA indicates Veterans Health Administration; AHA GWTG-CAD, American Heart Association's Get With The Guidelines—Coronary Artery Disease; ACTION/GWTG-STEMI, Acute Coronary Treatment and Intervention Outcomes Network/Get With The Guidelines—ST-Elevation Myocardial Infarction; ACTION/GWTG-NSTEMI, Acute Coronary Treatment and Intervention Outcomes Network/Get With The Guidelines—Non-ST-Elevation Myocardial Infarction; AMI, acute myocardial infarction; NM, not measured; LDL, low-density lipoprotein; ARB, angiotensin receptor blocker; ACEI, angiotensin-converting enzyme inhibitor; LVEF, left ventricular ejection fraction.

Values are percentages.

\*VHA: AMI patients.

†National Medicare and Medicaid: AMI patients.

‡AHA GWTG-CAD: Patients admitted with a cardiovascular event. In the GWTG-CAD registry, the in-hospital mortality rate was 4.5% (excludes transfer-out patients; if discharge status was missing, it was assumed to be "no."). The mean length of hospital stay was 5.0 days (median 3.0 days).

§ACTION Registry: STEMI and NSTEMI patients were reported separately. Patients must have been admitted with acute ischemic symptoms within the previous 24 hours, typically reflected by a primary diagnosis of STEMI or NSTEMI. Patients who were admitted for any other clinical condition were not eligible.

||Indicates the 7 key achievement measures targeted in GWTG-CAD. The composite quality-of-care measure for 2009 was 94.4%. The composite quality-of-care measure indicates performance on the provision of several elements of care. It is computed by summing the numerators for each key performance measure across the population of interest to create a composite numerator (all the care that was given), summing the denominators for each measure to form a composite denominator (all the care that should have been given), and reporting the ratio (the percentage of all the needed care that was given).

¶Lipid-lowering therapy among patients with LDL >130 mg/dL.

**Table 20-2. Heart Failure Quality-of-Care Measures, 2009**

Quality-of-Care Measure	National		VHA
	Medicare and Medicaid	AHA-GWTG-HF	
LVEF assessment	97	98*	100
ARB/ACEI at discharge for patients with left ventricular systolic dysfunction	93	93*	96
Complete discharge instructions	85	91*	96
Adult smoking cessation advice/counseling	98	98*	98
$\beta$ -blockers at discharge for patients with LVSD, no contraindications	NM	93*	90
Anticoagulation for AF or atrial flutter, no contraindications	NM	69	94

AHA GWTG-HF indicates American Heart Association Get With The Guidelines—Heart Failure; VHA, Veterans Health Administration; LVEF, left ventricular ejection fraction; ARB, angiotensin receptor blocker; ACEI, angiotensin-converting enzyme inhibitor; LVSD, left ventricular systolic dysfunction; NM, not measured; AF, atrial fibrillation.

Values are percentages.

In the GWTG registry, mechanical ventilation was required in 3.0% of patients. In-hospital mortality rate was 3.0%, and mean length of hospital stay was 5.5 days (median 4.0 days).

\*Indicates the 5 key performance measures targeted in GWTG-HF. The composite quality-of-care measure for 2009 was 94.5%. The composite quality-of-care measure indicates performance on the provision of several elements of care. It is computed by summing the numerators for each key performance measure across the population of interest to create a composite numerator (all the care that was given), summing the denominators for each measure to form a composite denominator (all the care that should have been given), and reporting the ratio (the percentage of all the needed care that was given).

**Table 20-3. Time Trends in GWTG-CAD Acute Coronary Syndrome Quality-of-Care Measures, 2006–2009**

Quality-of-Care Measure	2006	2007	2008	2009
Aspirin within 24 h of admission*	94.7	92.8	91.2	90.9
Aspirin at discharge*	94.4	95.8	94.9	95.5
$\beta$ -blockers at discharge*	92.8	94.6	94.5	94.9
Lipid-lowering medication at discharge	84.5	85.6	81.6	86.8
Lipid therapy at discharge if LDL >100 mg/dL*	89.1	90.7	91.9	92.5
ARB/ACEI at discharge for patients with left ventricular ejection fraction <40%*	87.3	91.1	91.9	91.9

Adult smoking cessation advice/counseling*	94.3	97.4	98.4	98.4
Cardiac rehabilitation referral for AMI patients	71.1	63.6	52.0	49.1

GWTG indicates Get With The Guidelines; LDL, low-density lipoprotein cholesterol; ARB, angiotensin receptor blocker; ACEI, angiotensin-converting enzyme inhibitor; AMI, acute myocardial infarction.

Values are percentages.

GWTG-CAD: Patients admitted with cardiovascular event. In the GWTG-CAD registry. The in-hospital mortality was 4.5% (excludes transfer-out patients; if discharge status was missing, it was assumed to be “no”), and mean length of hospital stay was 5.0 days (median 3.0 days).

**Table 20-4. Time Trends in GWTG-HF Quality-of-Care Measures, 2006–2009**

Quality of Care Measure	2006	2007	2008	2009
Left ventricular ejection fraction assessment*	93.8	96.2	96.8	98.2
ARB/ACEI at discharge for patients with left ventricular systolic dysfunction*	85.5	89.1	91.6	93.0
Complete discharge instructions*	78.8	84.8	88.5	90.9
Adult smoking cessation advice/counseling*	90.8	94.7	97.1	97.6
$\beta$ -blockers at discharge for patients with LVSD, no contraindications*	89.9	90.2	92.5	92.7
Anticoagulation for atrial fibrillation or atrial flutter, no contraindications	62.9	61.6	60.7	68.9

GWTG-HF indicates Get With The Guidelines–Heart Failure; ARB, angiotensin receptor blocker; ACEI, angiotensin-converting enzyme inhibitor; LVSD, left ventricular systolic dysfunction.

Values are percentages.

In the GWTG registry, mechanical ventilation was required in 3.0% of patients. In-hospital mortality was 3.0%, and mean length of hospital stay was 5.5 days (median 4.0 days).

\*Indicates the 5 key achievement measures targeted in GWTG-HF. The composite quality of care measure for 2009 was 94.5%. The composite quality-of-care measure indicates performance on the provision of several elements of care. It is computed by summing the numerators for each key achievement measure across the population of interest to create a composite numerator (all the care that was given), summing the denominators for each measure to form a composite denominator (all the care that should have been given), and reporting the ratio (the percentage of all the needed care that was given).

**Table 20-5. Time Trends in GWTG-Stroke Quality-of-Care Measures, 2006–2009**

Quality of Care Measure	2006	2007	2008	2009
Thrombolytic complications: IV tPA and life-threatening, serious systemic hemorrhage	20.8	17.3	16.1	15.1
Antithrombotics <48 h after admission*	94.8	95.8	96.0	96.2
DVT prophylaxis by second hospital day*	85.3	88.9	92.2	92.7
Antithrombotics at discharge*	94.1	95.1	97.0	97.8
Anticoagulation for atrial fibrillation at discharge*	88.2	89.5	93.1	93.5
Therapy at discharge if LDL >100 mg/dL or LDL not measured or on therapy at admission*	70.3	76.3	82.1	86.2
Counseling for smoking cessation*	86.1	92.2	94.3	96.2
Lifestyle changes recommended for BMI >25 kg/m <sup>2</sup>	42.5	45.7	51.7	57.3
Composite quality-of-care measure†	85.9	88.9	91.7	93.3

GWTG indicates Get With The Guidelines; IV, intravenous; tPA, tissue-type plasminogen activator; DVT, deep venous thrombosis; LDL, low-density lipoprotein; BMI, body mass index.

Values are percentages. In-hospital mortality for the 2009 patient population was 6.9%, and mean length of hospital stay was 5.3 days (median 3.0 days).

\*Indicates key performance measures targeted in GWTG-Stroke.

†The composite quality-of-care measure indicates performance on the provision of several elements of care. It is computed by summing the numerators for each key achievement measure across the population of interest to create a composite numerator (all the care that was given), summing the denominators for each measure to form a composite denominator (all the care that should have been given), and reporting the ratio (the percentage of all the needed care that was given).

**Table 20-6. Additional ACTION-GWTG Quality-of-Care Metrics for ACS Care, 2009**

Quality Metrics	Overall	STEMI	NSTEMI
ECG within 10 min of arrival	59.1	70.4	53.7
Aspirin within 24 h of arrival	94.4	96.3	93.2
Anticoagulant within 24 h of arrival for NSTEMI	87.9	NA	87.9
Excessive initial UFH dose	60.2	61.7	58.7
Excessive initial enoxaparin dose	12.0	11.5	12.1
Excessive GP IIb/IIIa dose	8.5	8.6	8.4
ADP receptor within 24 h of arrival for STEMI	92.9	92.9	NA
ADP receptor on discharge for revascularized AMI population	91.5	95.2	87.8
ADP receptor on discharge for medically treated AMI population	59.8	65.0	59.1
Aldosterone-blocking agents on discharge	6.0	6.3	5.8
Documentation of LDL-C level in hospital record	82.9	84.4	81.5

ACTION indicates Acute Coronary Treatment and Intervention Outcomes Network; GWTG, Get With The Guidelines; ACS, acute coronary syndrome; STEMI, ST-elevation myocardial infarction; NSTEMI, non-ST-elevation myocardial infarction; ECG, electrocardiogram; NA, not applicable; UFH, unfractionated heparin; GP, glycoprotein; ADP, adenosine triphosphate; AMI, acute myocardial infarction; LDL-C, low-density lipoprotein cholesterol.

**Table 20-7. National Committee for Quality Assurance Health Plan Employer Data and Information Set Measures of Care**

	Commercial, %	Medicare, %	Medicaid, %
<b>Acute MI</b>			
β-blocker persistence*	75.0	79.7	73.6
<b>Cholesterol management for patients with CAD</b>			
Cholesterol screening	88.9	88.6	79.6
LDL control (<100 mg/dL)	59.7	56.7	40.1
<b>Hypertension</b>			
BP <140/90 mm Hg	63.4	58.5	55.8
<b>DM</b>			
HbA <sub>1c</sub> testing	89.0	88.3	80.5
HbA <sub>1c</sub> >9.0%	28.4	29.4	44.8
Eye examination performed	56.5	60.8	52.8
LDL cholesterol screening	84.8	86.3	74.1
LDL cholesterol <100 mg/dL	45.5	48.7	33.8
Monitoring nephropathy	82.4	87.9	76.6
BP <130/80 mm Hg	33.4	31.8	30.7
BP <140/90 mm Hg	65.6	59.5	56.9
Advising smokers to quit	76.7	N/A	69.3

MI indicates myocardial infarction; CAD, coronary artery disease; LDL, low-density lipoprotein; BP, blood pressure; DM, diabetes mellitus; HbA<sub>1c</sub>, glycosylated hemoglobin.

\*β-blocker persistence: Received persistent β-blocker treatment for 6 months after hospital discharge for acute MI.

**Table 20-8. Timely Reperfusion for ACS and Stroke**

Quality-of-Care Measure	VHA*	National Medicare and Medicaid*	GWTG-CAD†	ACTION-GWTG-STEMI‡	GWTG-Stroke
<b>ACS</b>					
tPA within 30 min	73	52	27	69	N/A
PCI within 90 min	55	86	78	90	N/A
<b>Stroke</b>					
IV tPA in patients who arrived <2 h after symptom onset§	NA	NA	NA	NA	73.1
IV tPA in patients who arrived <3 h after symptom onset	NA	NA	NA	NA	67.1
No IV tPA (contraindicated/warning)	NA	NA	NA	NA	82.4

ACS indicates acute coronary syndrome; VHA, Veterans Health Administration; GWTG-CAD, Get With The Guidelines—Coronary Artery Disease; ACTION-GWTG-STEMI, Acute Coronary Treatment and Intervention Outcomes Network/Get With The Guidelines—ST-elevation myocardial infarction; tPA, tissue-type plasminogen activator; NA, not applicable; PCI, percutaneous coronary intervention; IV, intravenous.

Values are percentages.

\*Acute myocardial infarction patients.

†GWTG-CAD: Patients admitted with a cardiovascular event. In the GWTG-CAD registry, the in-hospital mortality rate was 4.5% (excludes transfer-out patients; if discharge status was missing, it was assumed to be “no.”). The mean length of hospital stay was 5.0 days (median 3.0 days).

‡ACTION Registry: STEMI and NSTEMI patients were reported separately. Patients must have been admitted with acute ischemic symptoms within the previous 24 hours, typically reflected by a primary diagnosis of ST-elevation myocardial infarction or non-ST-elevation myocardial infarction. Patients who were admitted for any other clinical condition were not eligible.

§Indicates 1 of the 7 key performance measures targeted in GWTG-Stroke.

**Table 20-9. Quality of Care by Race/Ethnicity and Sex in the GWTG-CAD Program, 2009**

Quality-of-Care Measure	Race/Ethnicity			Sex	
	White	Black	Hispanic	Men	Women
Aspirin at admission*	98.0	98.2	97.9	97.9	97.5
Aspirin at discharge*	96.1	96.3	93.5	96.7	94.5
β-Blockers at discharge*	96.0	97.0	94.2	96.4	94.5

ACEI at discharge for AMI patients	64.6	70.1	71.1	67.3	61.7
ACEI in LVSD patients	84.8	83.1	82.4	84.4	81.6
ACEI/ARB for LVSD patients at discharge*	93.4	93.0	93.0	92.6	92.1
Lipid therapy at discharge	87.5	85.9	79.4	88.5	82.6
Lipid therapy at discharge if LDL >100 mg/dL*	93.5	90.7	91.5	95.2	88.2
Patients with last BP <140/90 mm Hg	80.6	72.8	79.8	81.6	76.9
Smoking cessation counseling*	98.5	98.7	99.0	98.3	98.1
Referral to cardiac rehabilitation for AMI patients	51.5	46.2	52.6	49.6	48.3
Composite quality-of-care measure†	96.4	96.5	94.8	96.7	94.9

GWTG-CAD indicates Get With the Guidelines—Coronary Artery Disease; ACEI, angiotensin-converting enzyme inhibitor; AMI, acute myocardial infarction; LVSD, left ventricular systolic dysfunction; ARB, angiotensin receptor blocker; LDL, low-density lipoprotein; BP, blood pressure.

Values are percentages.

\*Indicates the 6 key achievement measures targeted in GWTG-CAD.

†The composite quality-of-care measure indicates performance on the provision of several elements of care. It is computed by summing the numerators for each key achievement measure across the population of interest to create a composite numerator (all the care that was given), summing the denominators for each measure to form a composite denominator (all the care that should have been given), and reporting the ratio (the percentage of all the needed care that was given).

**Table 20-10. Quality of Care by Race/Ethnicity and Sex in the GWTG-HF Program, 2009**

Quality-of-Care Measure	Race/Ethnicity			Sex	
	White	Black	Hispanic	Men	Women
Complete set of discharge instructions*	90.8	91.7	91.4	91.3	90.2
Measure of LV function*	98.3	98.9	97.3	98.4	98.0
ACEI or ARB at discharge for patients with LVSD, no contraindications*	92.0	94.2	94.0	92.8	93.0
Smoking cessation counseling, current smokers*	96.6	99.1	96.7	97.8	97.1
β-Blockers at discharge for patients with LVSD, no contraindications*	92.8	92.0	91.2	93.2	92.0
Hydralazine/nitrates at discharge for patients with LVSD, no contraindications	NM	12.2	NM	13.1†	10.1†
Anticoagulation for atrial fibrillation or atrial flutter, no contraindications	69.2	67.2	72.3	71.6	66.1
Composite quality-of-care measure‡	94.4	95.1	94.0	94.7	94.2

GWTG-HF indicates Get With The Guidelines—Heart Failure; LV, left ventricular; ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; LVSD, left ventricular systolic dysfunction; NM, not measured.

Values are percentages.

\*Indicates the 5 key achievement measures targeted in GWTG-HF.

†For black patients only.

‡The composite quality-of-care measure indicates performance on the provision of several elements of care. It is computed by summing the numerators for each key achievement measure across the population of interest to create a composite numerator (all the care that was given), summing the denominators for each measure to form a composite denominator (all the care that should have been given), and reporting the ratio (the percentage of all the needed care that was given).

**Table 20-11. Quality of Care by Race/Ethnicity and Sex in the GWTG-Stroke Program, 2009**

Quality-of-Care Measure	Overall	Race/Ethnicity			Sex	
		White	Black	Hispanic	Male	Female
IV tPA in patients who arrived <2 h after symptom onset*	73.1	73.2	72.7	73.0	74.6	71.7
IV tPA in patients who arrived <3 h after symptom onset	67.1	67.0	67.6	66.9	69.0	65.4
No IV-tPA (contraindicated/warning)	82.4	82.6	82.1	80.4	83.0	81.9
Thrombolytic complications: IV tPA and life-threatening, serious systemic hemorrhage	15.1	15.1	13.7	16.2	14.3	16.0
Antithrombotics <48 h after admission*	96.2	96.4	95.8	95.3	96.6	95.8
DVT prophylaxis by second hospital day*	92.7	92.8	92.9	91.7	93.0	92.4
Antithrombotics at discharge*	97.8	97.9	97.3	96.9	98.1	97.5
Anticoagulation for atrial fibrillation at discharge*	93.5	93.8	91.9	91.3	93.9	93.2
Therapy at discharge if LDL >100 mg/dL or LDL not measured or on therapy at admission*	86.2	86.0	86.7	86.7	88.8	84.0
Counseling for smoking cessation*	96.2	96.5	96.5	94.8	96.4	96.1
Lifestyle changes recommended for BMI >25 kg/m <sup>2</sup>	57.3	56.6	58.7	62.6	57.5	57.1
Composite quality-of-care measure†	93.3	93.3	93.4	92.6	94.1	92.5

GWTG-Stroke indicates Get With The Guidelines–Stroke; IV tPA, intravenous tissue-type plasminogen activator; DVT, deep venous thrombosis; LDL, low-density lipoprotein; BMI, body mass index.

Values are percentages.

In-hospital mortality for the 2009 patient population was 6.9%, and mean length of hospital stay was 5.3 days (median 3.0 days).

\*Indicates the 7 key performance measures targeted in GWTG-Stroke.

†The composite quality-of-care measure indicates performance on the provision of several elements of care. It is computed by summing the numerators for each key achievement measure across the population of interest to create a composite numerator (all the care that was given), summing the denominators for each measure to form a composite denominator (all the care that should have been given), and reporting the ratio (the percentage of all the needed care that was given).

## 21. Medical Procedures

See Tables 21-1 and 21-2 and Charts 21-1 through 21-3.

- The total number of inpatient cardiovascular operations and procedures increased 27%, from 5 382 000 in 1997 to 6 846 000 in 2007 (NHLBI computation based on NCHS annual data). Data from the NHDS were examined for trends from 1990 to 2004 for use of PCI and CABG and in-hospital mortality rate due to PCI and CABG by sex.<sup>1</sup>
  - Discharge rates (per 10 000 population) for PCI increased 58%, from 37.2 in 1990–1992 to 59.2 in 2002–2004.
  - Discharge rates for CABG increased from 34.1 in 1990–1992 to 38.6 in 1996–1998, then declined to 25.2 in 2002–2004.
  - In 1990–1992, discharge rates for CABG were 53.5 for males and 18.1 for females; these rates increased through 1996–1998, then declined to 38.8 and 13.6, respectively, in 2002–2004. The magnitude of these declines decreased by age decile and were essentially flat for both men and women 75 years of age.
  - PCI discharge rates increased from 54.5 for males and 23.0 for females to 83.0 and 38.7 over the 15-year time interval. In 2002–2004, discharge rates for men and women 65 to 74 years of age were 135.1 and 64.0, respectively. For those 75 years of age, the rates were 128.7 and 69.0, respectively.
  - In-hospital mortality rate (deaths per 100 CABG discharges) declined from 4.3 to 3.5 in 2002 to 2004 despite an increase in Charlson comorbidity index. The mortality rate declined in all age and sex subsets, but especially in women.
  - PCI mortality remained stable over the 15-year interval.
- Data from the Acute Care Tracker database were used to estimate the population-based rates per 100 000 population

### Abbreviations Used in Chapter 21

AHA	American Heart Association
CABG	coronary artery bypass graft
CHF	congestive heart failure
D2B	door-to-balloon
GWTG-CAD	Get With The Guidelines—Coronary Artery Disease
HD	heart disease
NCHS	National Center for Health Statistics
NHDS	National Hospital Discharge Survey
NHLBI	National Heart, Lung, and Blood Institute
PCI	percutaneous coronary intervention
PTCA	percutaneous transluminal coronary angioplasty
STEMI	ST-elevation myocardial infarction
STS	Society of Thoracic Surgeons
STS NCD	Society of Thoracic Surgeons' National Adult Cardiac Database
TOF	tetralogy of Fallot

for PCI and CABG procedures from 2002 to 2005, standardized to the 2005 US population?:

- Adjusted for age and sex, the overall rate for coronary revascularization declined from 382 to 358 per 100 000. PCI rates during hospitalization increased from 264 to 267 per 100 000, whereas CABG rates declined from 121 to 94.
- Data from men and women enrolled in Medicare from 1992 to 2001 suggest that efforts to eliminate racial disparities in the use of high-cost cardiovascular procedures (PCI, CABG, and carotid endarterectomy) were unsuccessful.<sup>3</sup>
  - In 1992, among women, the age-standardized rates of carotid endarterectomy were 1.59 per 1000 enrollees for whites and 0.64 per 1000 enrollees for blacks. By 2002, the rates were 2.42 per 1000 enrollees among white women and 1.15 per 1000 enrollees among black women. For men, the difference in rates between whites and blacks remained the same. In 1992, the rates were 3.13 per 1000 enrollees among white men and 0.82 per 1000 enrollees among black men; in 2001, the rates were 4.42 and 1.44, respectively.

### Cardiac Catheterization and PCI

- From 1997 to 2007, the number of cardiac catheterizations decreased slightly, from 1 112 000 to 1 059 000 annually.
- In 2007, an estimated 622 000 patients underwent PCI (previously referred to as percutaneous transluminal coronary angioplasty, or PTCA) procedures in the United States (NHLBI tabulation, NHDS, NCHS).
- In 2007, ≈67% of PCI procedures were performed on men, and ≈51% were performed on people ≥65 years of age (NHDS, NCHS).
- The mortality rate for PCI has remained stable despite an increase in risk.<sup>1</sup>
- In 2006, ≈76% of stents implanted during PCI were drug-eluting stents compared with 24% that were bare-metal stents.<sup>4</sup>
- In a study of nontransferred patients with STEMI treated with primary PCI from July 2006 to March 2008, there was significant improvement over time in the percentage of patients receiving PCI within 90 minutes, from 54.1% from July to September 2006 to 74.1% from January to March 2008 among hospitals participating in the GWTG-CAD program. This improvement was seen whether or not hospitals joined the D2B Alliance during that period.<sup>5</sup>

### Cardiac Open Heart Surgery

The NHDS (NCHS) estimates that in 2007, in the United States, 232 000 patients underwent a total of 408 000 coronary artery bypass procedures (defined by procedure codes). CABG volumes have declined nationally since 1998. Risk-adjusted mortality for CABG has declined significantly over the past decade:

- Data from the Society of Thoracic Surgeons' National Adult Cardiac Database (STS NCD), which voluntarily collects data from ≈80% of all hospitals that perform

CABG in the United States, indicate that a total of 163 149 procedures involved CABG in 2009.<sup>6</sup>

- Data from the STS NCD document a 50% decline in the risk-adjusted mortality rate despite a significant increase in preoperative surgical risk.<sup>7</sup>

### **Congenital Heart Surgery, 2005 to 2008 (From the Society of Thoracic Surgeons [STS])**

There were 91 639 procedures performed from July 2005 to June 2009. The in-hospital mortality rate was 3.4% in 2009. The 5 most common diagnoses were the following: Patent ductus arteriosus (7.8%); hypoplastic left heart syndrome (7.0%); ventricular septal defect, type 2 (5.7%); tetralogy of Fallot (5.3%); and cardiac, other (4.7%).<sup>8</sup>

### **Congenital Heart Surgery, 1998 to 2002 (From STS)**

There were 16 920 procedures performed from 1998 to 2002 at 18 centers. In 2002, there were 4208 procedures performed. The in-hospital mortality ranged from 5.7% in 1998 to 4.3% in 2002. Of these procedures, ≈46% were performed in children >1 year old, ≈32% in infants between 29 days and 1 year of age, and ≈22% in neonates (<29 days old). The conditions for which these procedures were most commonly performed were the following: Patent ductus arteriosus (6.5%), ventricular septal defect (6.4%), and TOF (6.0%).

### **Heart Transplantations**

In 2009, 2211 heart transplantations were performed in the United States. There are 249 transplant hospitals in the United States, 127 of which perform heart transplantations (United Network for Organ Sharing, Web site accessed June 24, 2010).

- Of the recipients, 72.1% are male, and 67.6% are white; 19.0% are black, whereas 9.1% are Hispanic; 25.5% are <35 years of age, 17.9% are 35 to 49 years of age, and 56.6% are ≥50 years of age.
- As of June 25, 2010, for transplants that occurred between 1997 and 2004, the 1-year survival rate for males was 88.0%, and for females, it was 86.2%; the 3-year rates were 79.3% for males and 77.2% for females; and the 5-year rates were 73.1% for males and 69.0% for females. The 1-, 3-, and 5-year survival rates for white cardiac transplant patients were 87.1%, 79.2%, and 72.5%, respectively. For black patients, they were 85.5%, 71.9%, and 62.3%, respectively. For Hispanic patients, they were 88.7%, 77.6%, and 72.1%, respectively.

- As of June 25, 2010, 3153 patients were on the transplant waiting list for a heart transplant and 80 patients were on the list for a heart/lung transplant.

### **Cardiovascular Healthcare Expenditures**

An analysis of claims and enrollment data from the Continuous Medicare History Sample and from physician claims from 1995 to 2004 was used to evaluate the conditions that contributed to the most expensive 5% of Medicare beneficiaries.<sup>9</sup>

- Ischemic HD, CHF, and cerebrovascular disease, respectively, constituted 13.8%, 5.9%, and 5.7% of the conditions of all beneficiaries in 2004. In patients in the top 5% overall for all expenditures, the respective figures were 39.1%, 32.7%, and 22.3% for these cardiovascular conditions.

ICD-9-CM indicates *International Classification of Diseases, 9th Revision, Clinical Modification*; PCI, percutaneous coronary intervention.

Ellipses (. . .) indicate data not available.

These data do not reflect any procedures performed on an outpatient basis. Many more procedures are being performed on an outpatient basis. Some of the lower numbers in this table compared with 2006 probably reflect this trend.

\*Breakdowns are not available for some procedures, so entries for some categories do not add to totals. These data include codes for which the estimated number of procedures is <5000. Categories of such small numbers are considered unreliable by NCHS and in some cases may have been omitted.

†Estimate should be used with caution because it may be unreliable or does not meet standards of reliability or precision.

§Because ≥1 procedure codes are required to describe the specific bypass procedure performed, it is impossible from these (mixed) data to determine the average number of grafts per patient.

||Totals include procedures not shown here.

¶This estimate includes angioplasty and stent insertions for noncoronary arteries.

Data derived from the National Hospital Discharge Survey/National Center for Health Statistics, 2007. Estimates are based on a sample of inpatient records from short-stay hospitals in the United States.

## 22. Economic Cost of Cardiovascular Disease

See Tables 22-1 and 22-2 and Charts 22-1 and 22-2.

The total direct and indirect cost of CVD and stroke in the United States for 2007 is an estimated \$286 billion (Table 22-1; Chart 22-1). This figure includes \$167 billion in expenditures (direct costs, which include the cost of physicians and other professionals, hospital services, prescribed medications, and home health care) and \$119 billion in lost productivity resulting from premature mortality (indirect costs).

The \$286 billion is substantially lower than the estimate in the 2010 Statistical Update. Previously, annual estimates were based on the assumption that the proportion of CVD costs to total costs for physician services, hospital care, drugs, etc that were reported in a major study of 1995 direct costs were still valid in the current year. Each year, the 1995 proportions were applied to current National Health Expenditure Accounts (NHEA) of aggregate personal healthcare expenditures from the CMS to estimate direct costs.<sup>1</sup> Because the assumption becomes weaker each year, the decision was made to use another data source.

The previous estimates of indirect morbidity costs of CVD were also unsatisfactory because they were based on extrapolations from 1980 data and were only corrected for annual inflation. In addition, the estimates for the specific CVDs were based on crude assumptions that used data for bed disability days. The true indirect morbidity costs of lost productivity due to CVD illnesses are probably large, but data to estimate them are inadequate.

Thus, the following changes were made:

- The annual direct cost estimates are available on the Web site of the nationally representative MEPS of the AHRQ.<sup>1</sup>
- The estimates of indirect morbidity costs will be discontinued until adequate estimates can be made.
- Estimates of all direct costs and indirect mortality costs are limited to the latest year for which MEPS data are available, 2007, rather than projecting costs to 2011.

The advantages of using data from MEPS are as follows:

- MEPS is designed to estimate healthcare utilization and expenditures linked to specific medical conditions for the US civilian noninstitutionalized population, and the estimates are based on person-level survey data directly linked to patient care events.<sup>2</sup>

### Abbreviations Used in Chapter 22

AHRQ	Agency for Healthcare Research and Quality
CHD	coronary heart disease
CMS	Centers for Medicare & Medicaid Services
CVD	cardiovascular disease
HD	heart disease
HF	heart failure
MEPS	Medical Expenditure Panel Survey
NHEA	National Health Expenditure Accounts

- The estimates are available annually on the MEPS Web site and can be customized by age, sex, and race/ethnicity.<sup>1</sup>
- MEPS data have been used extensively in scientific publications and reports.<sup>2</sup>

Some disadvantages of using data from MEPS are as follows:

- MEPS cost estimates cover a narrower population and a narrower range of healthcare expenditures than the NHEA estimates.<sup>3</sup> For example, costs of nursing home care are not included.
- The MEPS data are based on household reports, which are subject to underreporting and misreporting of individual medical events and to annual fluctuation.<sup>2</sup>
- The \$286 billion estimate includes some double counting of costs for individuals classified in more than 1 of the 4 CVD groups.
- Direct costs for CHD and HF are not included in the list of conditions on the MEPS Web site.
- Direct costs for hypertension exclude costs for hypertensive HD, which are included in the HD costs. There is no estimate for total hypertension.

There is no change in the way mortality costs are estimated except to limit estimates to the same year (2007) as for direct costs (personal communication [unpublished table of present value of lifetime earnings by age and sex, United States, 2005] from Wendy Max, PhD, University of California at San Francisco, and data from the National Center for Health Statistics<sup>4</sup> and the US Census Bureau<sup>5</sup>).

### Most Costly Diseases

CVD and stroke accounted for 15% of the total health expenditures in 2007.<sup>2,6</sup> The total cost and the indirect mortality cost estimates for CVD are higher than for any other major diagnostic group.<sup>1</sup> By way of comparison, CVD total direct and indirect costs shown in Table 22-1 are higher than the official National Cancer Institute estimates for cancer and benign neoplasms in 2010, which were cited as \$264 billion total, \$103 billion direct, \$21 billion indirect morbidity, and \$140 billion indirect cost of mortality.<sup>7</sup>

Table 22-2 shows direct and indirect costs for CVD by sex and by 2 broad age groups. Chart 22-2 shows total direct costs for the 13 leading chronic diseases in the MEPS list.

**Table 22-1. Estimated Direct and Indirect Costs (in Billions of Dollars) of Cardiovascular Disease and Stroke: United States, 2007 (Based on New Data Sources and Estimation Methods)**

	Heart Disease*	Stroke	Hypertensive Disease†	Other Circulatory Conditions	Total Cardiovascular Disease
Direct costs‡					
Hospital inpatient stays	49.8	17.9	6.2	11.8	85.7
Hospital emergency room visits	3.9	0.6	0.6	0.2	5.3
Hospital outpatient or office-based provider visits	13.7	2.5	9.8	5.0	31.0
Home health care	6.3	2.9	3.6	1.1	13.9
Prescribed medicines	8.5	1.3	20.4	1.2	31.4
Total expenditures	82.2	25.2	40.6	19.3	167.4
Indirect costs§					
Lost productivity/mortality	95.3	15.7	2.9	5.3	119.2
Grand totals	177.5	40.9	43.5	24.6	286.6

Numbers do not add to total due to rounding.

\*This category includes coronary heart disease, heart failure, part of hypertensive disease, cardiac dysrhythmias, rheumatic heart disease, cardiomyopathy, pulmonary heart disease, and other or ill-defined heart diseases.

†Costs due to hypertensive disease are limited to hypertension without heart disease.

‡Medical Expenditure Panel Survey healthcare expenditures are estimates of direct payments for care of a patient with the given disease provided during the year, including out-of-pocket payments and payments by private insurance, Medicaid, Medicare, and other sources. Payments for over-the-counter drugs are not included. These estimates of direct costs do not include payments attributed to comorbidities. Total cardiovascular disease costs are the sum of costs for the 4 diseases but with some duplication.

§The Statistics Committee agreed to suspend presenting estimates of lost productivity due to morbidity until a better estimating method can be developed.

||Earnings of persons who died in 2007, discounted at 3%.

Sources: Estimates from the Household Component of the Medical Expenditure Panel Survey of the Agency for Healthcare Research and Quality for direct costs (2007).<sup>1</sup> Indirect mortality costs are based on 2007 counts of deaths by the National Center for Health Statistics and an estimated present value of lifetime earnings furnished for 2005 by Wendy Max (Institute for Health and Aging, University of California, San Francisco, 2009) and inflated to 2007 from mean earnings values reported by the US Census Bureau.<sup>4,5</sup>

All estimates prepared by Thomas Thom and Michael Mussolino, National Heart, Lung, and Blood Institute.

**Table 22-2. Costs of Total CVD in Billions of Dollars by Age and Sex: United States, 2007**

	Total	Sex		Age, y	
		Males	Females	<65	≥65
Direct costs	167.4	86.4	81.0	74.6	92.8
Indirect mortality	119.2	91.3	27.9	103.0	16.2
Total	286.6	177.7	108.9	177.6	109.0

CVD indicates cardiovascular disease.

Numbers may not add due to rounding.

Sources: See summary tables in related chapters in this Update. For more data on congenital defects, see Chapter 8.

## 24. Glossary

- *Age-adjusted rates*—Used mainly to compare the rates of  $\geq 2$  communities or population groups or the nation as a whole over time. The American Heart Association (AHA) uses a standard population (2008), so these rates are not affected by changes or differences in the age composition of the population. Unless otherwise noted, all death rates in this publication are age adjusted per 100 000 population and are based on underlying cause of death.
- *Agency for Healthcare Research and Quality (AHRQ)*—A part of the US Department of Health and Human Services, this is the lead agency charged with supporting research designed to improve the quality of healthcare, reduce the cost of healthcare, improve patient safety, decrease the number of medical errors, and broaden access to essential services. AHRQ sponsors and conducts research that provides evidence-based information on healthcare outcomes, quality, cost, use, and access. The information helps healthcare decision makers (patients, clinicians, health system leaders, and policy makers) make more informed decisions and improve the quality of healthcare services.
- *Bacterial endocarditis*—An infection of the heart's inner lining (endocardium) or of the heart valves. The bacteria that most often cause endocarditis are streptococci, staphylococci, and enterococci.
- *Body mass index (BMI)*—A mathematical formula to assess body weight relative to height. The measure correlates highly with body fat. It is calculated as weight in kilograms divided by the square of the height in meters ( $\text{kg}/\text{m}^2$ ).
- *Centers for Disease Control and Prevention/National Center for Health Statistics (CDC/NCHS)*—An agency within the US Department of Health and Human Services. The CDC conducts the Behavioral Risk Factor Surveillance System (BRFSS), an ongoing study. The NCHS also conducts or has conducted these studies (among others):
  - National Health Examination Survey (NHES I, 1960 to 1962; NHES II, 1963 to 1965; NHES III, 1966 to 1970)
  - National Health and Nutrition Examination Survey I (NHANES I, 1971 to 1974)
  - National Health and Nutrition Examination Survey II (NHANES II, 1976 to 1980)
  - National Health and Nutrition Examination Survey III (NHANES III, 1988 to 1994)
  - National Health and Nutrition Examination Survey (NHANES, 1999 to ...) (ongoing)
  - National Health Interview Survey (NHIS) (ongoing)
  - National Home and Hospice Care Survey (periodic)
  - National Hospital Discharge Survey (NHDS) (ongoing)
  - National Nursing Home Survey (periodic)
- *Centers for Medicare & Medicaid Services (CMS), formerly Health Care Financing Administration (HCFA)*—The federal agency that administers the Medicare, Medicaid, and Child Health Insurance programs.
- *Comparability ratio*—Provided by the NCHS to allow time-trend analysis from one *International Classification of Diseases (ICD)* revision to another. It compensates for the “shifting” of deaths from one causal code number to another. Its application to mortality based on one ICD revision means that mortality is “comparability modified” to be more comparable to mortality coded to the other ICD revision.
- *Coronary heart disease (CHD) (ICD-10 codes I20–I25)*—This category includes acute myocardial infarction (I21–I22), other acute ischemic (coronary) heart disease (I24), angina pectoris (I20), atherosclerotic cardiovascular disease (I25.0), and all other forms of chronic ischemic CHD (I25.1–I25.9).
- *Death rate*—The relative frequency with which death occurs within some specified interval of time in a population. National death rates are computed per 100 000 population. Dividing the total number of deaths by the total population gives a crude death rate for the total population. Rates calculated within specific subgroups, such as age-specific or sex-specific rates, are often more meaningful and informative. They allow well-defined subgroups of the total population to be examined. Unless otherwise stated, all death rates in this publication are age adjusted and are per 100 000 population.
- *Diseases of the circulatory system (ICD codes I00–I99)*—Included as part of what the AHA calls “cardiovascular disease.” (See “Total cardiovascular disease” in this Glossary.)
- *Diseases of the heart*—Classification the NCHS uses in compiling the leading causes of death. Includes acute rheumatic fever/chronic rheumatic heart diseases (I00–I09), hypertensive heart disease (I11), hypertensive heart and renal disease (I13), coronary heart disease (I20–I25), pulmonary heart disease and diseases of pulmonary circulation (I26–I28), heart failure (I50), and other forms of heart disease (I29–I49, I50.1–I51). “Diseases of the heart” are not equivalent to “total cardiovascular disease,” which the AHA prefers to use to describe the leading causes of death.
- *Health Care Financing Administration (HCFA)*—See Centers for Medicare & Medicaid Services (CMS).
- *Hispanic origin*—In US government statistics, “Hispanic” includes people who trace their ancestry to Mexico, Puerto Rico, Cuba, Spain, the Spanish-speaking countries of Central or South America, the Dominican Republic, or other Spanish cultures, regardless of race. It does not include people from Brazil, Guyana, Suriname, Trinidad, Belize, or Portugal, because Spanish is not the first language in those countries. Most of the data in this update are for Mexican Americans or Mexicans, as reported by government agencies or specific studies. In many cases, data for all Hispanics are more difficult to obtain.
- *Hospital discharges*—The number of inpatients discharged from short-stay hospitals for whom some type of disease was the first-listed diagnosis. Discharges include those discharged alive, dead, or “status unknown.”
- *International Classification of Diseases (ICD) codes*—A classification system in standard use in the United States. The *International Classification of Diseases* is published by the World Health Organization. This system is reviewed and revised approximately every 10 to 20 years to ensure

its continued flexibility and feasibility. The 10th revision (ICD-10) began with the release of 1999 final mortality data. The ICD revisions can cause considerable change in the number of deaths reported for a given disease. The NCHS provides “comparability ratios” to compensate for the “shifting” of deaths from one ICD code to another. To compare the number or rate of deaths with that of an earlier year, the “comparability-modified” number or rate is used.

- **Incidence**—An estimate of the number of new cases of a disease that develop in a population, usually in a 1-year period. For some statistics, new and recurrent attacks, or cases, are combined. The incidence of a specific disease is estimated by multiplying the incidence rates reported in community- or hospital-based studies by the US population. The rates in this report change only when new data are available; they are not computed annually.
- **Major cardiovascular diseases**—Disease classification commonly reported by the NCHS; represents ICD codes I00–I78. The AHA does not use “major cardiovascular diseases” for any calculations. See “Total cardiovascular disease” in this Glossary.
- **Metabolic syndrome**—The metabolic syndrome is defined\* as the presence of any 3 of the following 5 diagnostic measures: Elevated waist circumference ( $\geq 102$  cm in men or  $\geq 88$  cm in women), elevated triglycerides ( $\geq 150$  mg/dL [1.7 mmol/L] or drug treatment for elevated triglycerides), reduced high-density lipoprotein (HDL) cholesterol ( $< 40$  mg/dL [0.9 mmol/L] in men,  $< 50$  mg/dL [1.1 mmol/L] in women, or drug treatment for reduced HDL cholesterol), elevated blood pressure ( $\geq 130$  mm Hg systolic blood pressure,  $\geq 85$  mm Hg diastolic blood pressure, or drug treatment for hypertension), and elevated fasting glucose ( $\geq 100$  mg/dL or drug treatment for elevated glucose).
- **Morbidity**—Incidence and prevalence rates are both measures of morbidity (ie, measures of various effects of disease on a population).
- **Mortality**—Mortality data for states can be obtained from the NCHS Web site (<http://cdc.gov/nchs/>), by direct communication with the CDC/NCHS, or from the AHA on request. The total number of deaths due to a given disease in a population during a specific interval of time, usually a year, are reported. These data are compiled from death certificates and sent by state health agencies to the NCHS. The process of verifying and tabulating the data takes  $\approx 2$  years.
- **National Heart, Lung, and Blood Institute (NHLBI)**—An institute in the National Institutes of Health in the US Department of Health and Human Services. The NHLBI conducts such studies as the following:
  - Framingham Heart Study (FHS) (1948 to ...) (ongoing)
  - Honolulu Heart Program (HHP) (1965 to 1997)
  - Cardiovascular Health Study (CHS) (1988 to ...) (ongoing)
  - Atherosclerosis Risk in Communities (ARIC) study (1985 to ...) (ongoing)

- Strong Heart Study (SHS) (1989 to 1992; 1991 to 1998)
- The NHLBI also published reports of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure and the Third Report of the Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III, or ATP III).

- **National Institute of Neurological Disorders and Stroke (NINDS)**—An institute in the National Institutes of Health of the US Department of Health and Human Services. The NINDS sponsors and conducts research studies such as these:
  - Greater Cincinnati/Northern Kentucky Stroke Study (GCNKSS)
  - Rochester (Minnesota) Stroke Epidemiology Project
  - Northern Manhattan Study (NOMAS)
  - Brain Attack Surveillance in Corpus Christi (BASIC) Project
- **Prevalence**—An estimate of the total number of cases of a disease existing in a population during a specified period. Prevalence is sometimes expressed as a percentage of population. Rates for specific diseases are calculated from periodic health examination surveys that government agencies conduct. Annual changes in prevalence as reported in this statistical update reflect changes in the population size. Changes in rates can be evaluated only by comparing prevalence rates estimated from surveys conducted in different years.

## Note

In the data tables, which are located in the different disease and risk factor categories, if the percentages shown are age adjusted, they will not add to the total.

- **Race and Hispanic origin**—Race and Hispanic origin are reported separately on death certificates. In this publication, unless otherwise specified, deaths of people of Hispanic origin are included in the totals for whites, blacks, American Indians or Alaska Natives, and Asian or Pacific Islanders according to the race listed on the decedent’s death certificate. Data for Hispanic people include all people of Hispanic origin of any race. See “Hispanic origin” in this Glossary.
- **Stroke (ICD-10 codes I60–I69)**—This category includes subarachnoid hemorrhage (I60); intracerebral hemorrhage (I61); other nontraumatic intracranial hemorrhage (I62); cerebral infarction (I63); stroke, not specified as hemorrhage or infarction (I64); occlusion and stenosis of pre-cerebral arteries not resulting in cerebral infarction (I65); occlusion and stenosis of cerebral arteries not resulting in cerebral infarction (I66); other cerebrovascular diseases (I67); cerebrovascular disorders in diseases classified elsewhere (I68); and sequelae of cerebrovascular disease (I69).
- **Total cardiovascular disease (ICD-10 codes I00–I99, Q20–Q28)**—This category includes rheumatic fever/rheumatic heart disease (I00–I09); hypertensive diseases (I10–I15);

\*According to criteria established by the American Heart Association/National Heart, Lung, and Blood Institute and published in *Circulation* (*Circulation*. 2005;112:2735–2752).

ischemic (coronary) heart disease (I20–I25); pulmonary heart disease and diseases of pulmonary circulation (I26–I28); other forms of heart disease (I30–I52); cerebrovascular disease (stroke) (I60–I69); atherosclerosis (I70); other diseases of arteries, arterioles, and capillaries (I71–I79); diseases of veins, lymphatics, and lymph nodes not classified elsewhere (I80–I89); and other and unspecified disorders of the circulatory system (I95–I99). When data are available, we include congenital cardiovascular defects (Q20–Q28).

- *Underlying cause of death or any-mention cause of death*—These terms are used by the NCHS when defining mortality. Underlying cause of death is defined by the World Health Organization as “the disease or injury which initiated the train of events leading directly to death, or the circumstances of the accident or violence which produced the fatal injury.” Contributing cause of death would be any other disease or condition that the decedent may also have had.

## Correction

In the article by Roger et al, “Heart Disease and Stroke Statistics—2011 Update: A Report From the American Heart Association”, which published ahead of print on December 15, 2010, and appeared in the February 1, 2011, issue of the journal (*Circulation*. 2011;123:e18–e209), a correction is needed.

On page e100, in Chart 6-7, the y axis title “Incidence per 100,000” was missing. The chart has been updated to include the y axis title.

This correction has been made to the current online version of the article, which is available at <http://circ.ahajournals.org/cgi/content/full/123/4/e18>.

© 2011 American Heart Association, Inc.
